Abstract

A nonlinear image-based visual servo control approach for pipeline following of fully-actuated Autonomous Underwater Vehicles (AUV) is proposed. It makes use of the binormalized Plücker coordinates of the pipeline borders detected in the image plane as feedback information while the system dynamics are exploited in a cascade manner in the control design. Unlike conventional solutions that consider only the system kinematics, the proposed control scheme accounts for the full system dynamics in order to obtain an enlarged provable stability domain. Control robustness with respect to model uncertainties and external disturbances is re-infused using integral corrections. Robustness and efficiency of the proposed approach are illustrated via both realistic simulations and experimental results on a real AUV.

Keywords: AUV, pipeline following, visual servoing, nonlinear control

1. Introduction

Underwater pipelines are widely used for transportation of oil, gas or other fluids from production sites to distribution sites. Laid down on the ocean floor, they are often subject to extreme conditions (temperature, pressure, humidity, sea current, vibration, salt, dust, etc.) that may lead to multiple problems such as corrosion, crack, joint failure, shock loading and leakage. Regular inspection, monitoring and maintenance of transportation pipelines are thus highly recommended for safe operation. Conventional pipeline monitoring and inspection methods generally consist in using surface ships and remotely operated underwater vehicles, with the consequence of slow response and mobilization time Christ and Wernli (2007). Moreover, methods involving human divers in deep water are difficult to implement due to the inhospitable environment with high health and safety risks. As underwater operations increase in scale and in complexity, the need for employing Autonomous Underwater Vehicles (AUV) increases Shukla and Karki (2016b,a). However, unlike unmanned aerial vehicles that have seen an impressive growth within the last two decades, progress in AUV research and development has been drastically hindered by the lack of global positioning systems, particularly due to the attenuation of electromagnetic waves in water.

The dynamics of AUVs are very nonlinear, with highly coupled translational and rotational dynamics Fossen (2002); Leonard (1997). Strong perturbations due to sea currents are also a source of complexity. Robust control design for AUVs thus has been extensively investigated. However, existing control approaches such as PID Allen et al. (1997), LQR Naeem et al. (2003), $H_{\infty}$ Fryxell et al. (1996), optimal control Spangelo and Egeland (1994), sliding mode control Josserand (2006); Lapiere et al. (2008), Lyapunov backstepping-based control Repoulias and Papadopoulos (2007), Aguiar and Pascoal (2007), Antonelli (2007) and Lyapunov model-based control Refsnes et al. (2008), Smallwood and Whitcomb (2004) mostly concern the pre-programmed trajectory tracking problem with little regard to the local topography of the environment.

In this paper, the problem of pipeline following for AUVs, commonly addressed by using either a monocular camera or an acoustic sensor such as side scan sonar (SSS) or multi-beam echo-sounder, is revisited. Control objectives often consist in steering the vehicle above the pipeline and in regulating its forward speed to a reference value that can be specified in advance or online by a human operator. Most existing works on this topic have been devoted to pipeline detection from camera images or SSS-images and to the derivation of the relative heading and position (up to a scale factor) of the AUV with respect to (w.r.t.) the pipeline. Basic kinematic controllers have been applied without considering the system dynamics Matsumoto and Yoshihiko (1995), Antich and Ortiz (2003), Inzartsev and Yoshihiko (1995); Antich and Ortiz (2003), Inzartsev and Pavin (2009); Baginski et al. (2011) with the consequence that the stability is not systematically guaranteed. Other control approaches for pipeline following have been proposed in a more “abstract” manner in the sense that error tracking terms are directly defined from image features Rives and Borrelly (1997); Krupinski et al. (2012). These image-based visual servoing (IBVS) approaches do not require much knowledge about the 3D environment and demand less computations. For instance, Rives and Borrelly (1997) proposed an IBVS controller for fully-actuated AUVs using polar representation of lines (i.e. pipeline borders) while exploiting the so-called task-function approach developed by Samson et al. (1991). However, only local stability is proved since both the image Jacobian and Hes-
sian matrices considered in the control design are evaluated at the desired pose in the image plane. The domain of convergence is thus impossible to be characterized. The present paper aims at extending the provable domain of stability by taking the vehicle dynamics into account and by adapting the IBVS control approach proposed in Mahony and Hamel (2005) to the case of AUVs. More precisely, image features used for control design are the bi-normalized Plücker coordinates [Plücker (1865)] of the pipeline borders. The resulting dynamic IBVS controller ensures the semi-global asymptotic stability.

This paper is organized as follows. Section 2 recalls notation and system modeling. In Section 3, the problem of pipeline following by visual servoing is formulated. Section 4 presents the proposed controller based on a cascade inner-outer loop control architecture, where the inner-loop controller stabilizes the vehicle’s velocities about a desired velocity setpoint and the outer-loop controller derives the desired velocities and their derivative w.r.t. Krupínski et al. (2012) are proposed in this paper. A number of improvements w.r.t. Krupínski et al. (2012) is an inertial frame. Let \( B = \{ B; \vec{b}_1, \vec{b}_2, \vec{b}_3 \} \) denote a frame attached to the AUV with origin coinciding with the vehicle’s CoB. Let \( C = \{ C; \vec{c}_1, \vec{c}_2, \vec{c}_3 \} \) be a frame attached to the camera, which is displaced from the origin of \( B \) by a vector \( \vec{BC} \) and whose base vectors are parallel to those of \( B \). The vectors of coordinates expressed in \( B \) of \( \vec{BC} \) and \( \vec{BC} \) are denoted as \( \vec{r}_C \in \mathbb{R}^3 \) and \( \vec{r}_C \in \mathbb{R}^3 \), respectively.

- The orientation (i.e. attitude) of \( B \) w.r.t. \( A \) is represented by the rotation matrix \( R \in \text{SO}(3) \). Let \( p \) and \( p_C \) denote the position of the origins of \( B \) and \( C \) expressed in \( A \), respectively. One has \( p = p_C - R \vec{r}_C \).

- The angular velocity vector of \( B \) relative to \( A \), expressed in \( B \), is denoted as \( \omega \). The translational (or linear) velocity vectors of the origins of \( B \) and \( C \), expressed in \( B \), are denoted as \( V_B = V_C = \omega \times r_C \) respectively. One has \( V_B = V_C = \omega \times r_C \).

- The vector of coordinates of the fluid (i.e. current) velocity in \( A \) and \( B \) are denoted as \( V_f \) and \( V_f \), respectively. In this paper, it is assumed that \( V_f \) is constant. \( V_f = V_f - V_f \) is the vector of coordinates of the CoB’s velocity w.r.t. the fluid.

- \( \{ e_1, e_2, e_3 \} \) denotes the canonical basis of \( \mathbb{R}^3 \). \( I_3 \) is the identity matrix of \( \mathbb{R}^{3 \times 3} \). For all \( u \in \mathbb{R}^3 \), the notation \( u_x \) denotes the skew-symmetric matrix associated with the cross product by \( u \), i.e., \( u_x v = u \times v, \forall v \in \mathbb{R}^3 \), \( \pi_x = I_3 - xx^\top \) is the projection onto the tangent space of the sphere \( S^2 \) of a point \( x \in S^2 \).

2.2. Recall on system modeling

Define \( W_h \triangleq [V_h; \Omega_h] \in \mathbb{R}^6 \). The total kinetic energy of the body-fluid system \( E_T \) is defined as the sum of the kinetic energy of the vehicle \( E_B \) and the one of the surrounding fluid \( E_F \), i.e. \( E_T = E_B + E_F \) with

\[
E_B = \frac{1}{2} W_h^\top M_B W_h, \text{ with } M_B \triangleq \begin{bmatrix} m & -m g \sin \theta & 0 \\ m g \cos \theta & m g \cos \theta & 0 \\ 0 & 0 & J_0 \end{bmatrix}
\]

\[
E_F = \frac{1}{2} W_h^\top M_f W_h, \text{ with } M_f \triangleq \begin{bmatrix} M_1^f & M_2^f \\ M_2^f & M_1^f \end{bmatrix}
\]

\( M_f \in \mathbb{R}^{6 \times 6} \) is referred to as the added mass matrix, which is approximately constant and symmetric [Fossen (2002)]. Thus,

\[
E_T = \frac{1}{2} W_h^\top M_T W_h, \text{ with } M_T = \begin{bmatrix} M & D \\ D & J \end{bmatrix}
\]

with \( M \triangleq M_1 + M_1^{fl} \), \( J \triangleq J_0 + M_2^{fl} \), \( D \triangleq m f g \cos \theta + M_2^{fl} \). The translational and rotational momentum arms are derived as

\[
\bullet \ A = \{ \overrightarrow{O; \vec{a}_1, \vec{a}_2, \vec{a}_3} \} \text{ is an inertial frame. Let } B = \{ B; \vec{b}_1, \vec{b}_2, \vec{b}_3 \} \text{ denote a frame attached to the AUV, with origin coinciding with the vehicle's CoB. Let } C = \{ C; \vec{c}_1, \vec{c}_2, \vec{c}_3 \} \text{ be a frame attached to the camera, which is displaced from the origin of } B \text{ by a vector } \vec{BC} \text{ and whose base vectors are parallel to those of } B. \text{ The vectors of coordinates expressed in } B \text{ of } \vec{BC} \text{ and } \vec{BC} \text{ are denoted as } \vec{r}_C \in \mathbb{R}^3 \text{ and } \vec{r}_C \in \mathbb{R}^3, \text{ respectively.}

\bullet \ The orientation (i.e. attitude) of } B \text{ w.r.t. } A \text{ is represented by the rotation matrix } R \in \text{SO}(3). \text{ Let } p \text{ and } p_C \text{ denote the position of the origins of } B \text{ and } C \text{ expressed in } A, \text{ respectively. One has } p = p_C - R \vec{r}_C. \text{ The angular velocity vector of } B \text{ relative to } A \text{, expressed in } B \text{, is denoted as } \omega \text{. The translational (or linear) velocity vectors of the origins of } B \text{ and } C \text{, expressed in } B \text{, are denoted as } V_B = V_C = \omega \times r_C \text{ respectively. One has } V_B = V_C = \omega \times r_C. \text{ The vector of coordinates of the fluid (i.e. current) velocity in } A \text{ and } B \text{ are denoted as } V_f \text{ and } V_f, \text{ respectively. In this paper, it is assumed that } V_f \text{ is constant. } V_f = V_f - V_f \text{ is the vector of coordinates of the CoB's velocity w.r.t. the fluid.} \text{ The canonical basis of } \mathbb{R}^3 \text{. } I_3 \text{ is the identity matrix of } \mathbb{R}^{3 \times 3}. \text{ For all } u \in \mathbb{R}^3 \text{, the notation } u_x \text{ denotes the skew-symmetric matrix associated with the cross product by } u \text{, i.e., } u_x v = u \times v, \forall v \in \mathbb{R}^3 \text{, } \pi_x = I_3 - xx^\top \text{ is the projection onto the tangent space of the sphere } S^2 \text{ of a point } x \in S^2. \text{ The total kinetic energy of the body-fluid system } E_T \text{ is defined as the sum of the kinetic energy of the vehicle } E_B \text{ and the one of the surrounding fluid } E_F \text{, i.e. } E_T = E_B + E_F \text{ with } \text{ with } M_B \triangleq \begin{bmatrix} m & -m g \sin \theta & 0 \\ m g \cos \theta & m g \cos \theta & 0 \\ 0 & 0 & J_0 \end{bmatrix} \end{bmatrix} \text{, with } M_f \triangleq \begin{bmatrix} M_1^f & M_2^f \\ M_2^f & M_1^f \end{bmatrix} \text{, } M_f \in \mathbb{R}^{6 \times 6} \text{ is referred to as the added mass matrix, which is approximately constant and symmetric [Fossen (2002)]}. \text{ Thus, } E_T = \frac{1}{2} W_h^\top M_T W_h, \text{ with } M_T = \begin{bmatrix} M & D \\ D & J \end{bmatrix} \text{ (1) with } M \triangleq M_1 + M_1^{fl}, \ J \triangleq J_0 + M_2^{fl}, \ D \triangleq m f g \cos \theta + M_2^{fl}. \text{ The translational and rotational momentum arms are derived as} \]

2. System Modelling

2.1. Notation

The following notation is introduced (Fig. 1).

- Let \( G \) and \( B \) denote the AUV’s center of mass (CoM) and center of buoyancy (CoB), respectively. Let \( m \) denote its mass and \( J_0 \) denote its inertia matrix w.r.t. the CoB. \( g \) denotes the gravity constant, i.e. \( g \approx 9.81(m/s^2) \).
The equations of motion are given by Leonard (1997)
\[
\begin{align*}
\dot{\pi}_h &= \frac{\partial E_T}{\partial \mathbf{V}_h} = \mathbf{M}\mathbf{V}_h + \mathbf{D}' \Omega \\
\dot{\pi}_\alpha &= \frac{\partial E_T}{\partial \Omega} = \mathbf{J}\Omega + \mathbf{D}\Omega
\end{align*}
\]
(2)

The equations of motion are given by Leonard (1997)

\[
\begin{align*}
\pi_{th} &= \pi_{th} \times \Omega + F_c + F_{gb} + F_d \\
\pi_{rh} &= \pi_{rh} \times \Omega + \pi_{bh} \times \mathbf{V}_h + \Gamma_c + \Gamma_g + \Gamma_d
\end{align*}
\]
(3a)

with positive damping matrices \( \mathbf{D} \), \( \mathbf{F} \) and \( \mathbf{C} \).

2.3. Model for control design

The momentum terms \( \hat{\mathbf{M}} \) and their dynamics \( \mathbf{F}_c \) involve unknown current velocity \( \mathbf{V}_c \), thereby complicating the control design process. Therefore, System (3) can be rewritten as follows

\[
\begin{align*}
\mathbf{p} &= \mathbf{R}\mathbf{V} \\
\mathbf{R} &= \mathbf{R}\dot{\Omega}_e \\
\dot{\mathbf{P}}_t &= \dot{\mathbf{P}}_t \times \dot{\mathbf{U}} + \mathbf{F}_c + \mathbf{F}_g + \mathbf{F}_d + \mathbf{F}_f \\
\dot{\mathbf{P}}_l &= \dot{\mathbf{P}}_l \times \dot{\mathbf{U}} + \dot{\mathbf{P}}_b \times \mathbf{V}_h + \dot{\mathbf{C}} + \dot{\mathbf{C}} + \dot{\mathbf{C}}
\end{align*}
\]
(4)

with new momentum and dissipative force terms (compared to (3))

\[
\begin{align*}
\hat{\mathbf{M}} &= \mathbf{M} + \mathbf{D}' \Omega, \quad \hat{\mathbf{C}} = \mathbf{C} + \mathbf{D}\Omega
\end{align*}
\]

and new dissipative force terms (compared to (3))

\[
\mathbf{F}_d = \mathbf{D}\mathbf{V}_d = \mathbf{D}(\mathbf{V}_d)
\]

and “disturbance” terms \( \mathbf{C}_d \) and \( \mathbf{C}_f \) given by

\[
\begin{align*}
\Delta C &= \mathbf{M}\mathbf{V}_f + \mathbf{D}\mathbf{V}_f \\
\Delta F &= \mathbf{M}\mathbf{V}_f + \mathbf{D}\mathbf{V}_f
\end{align*}
\]

The disturbance terms \( \Delta C \) and \( \Delta F \) vanish if \( \mathbf{V}_f = 0 \). Otherwise, they should be addressed using either an estimator or integral compensation actions.

In the sequel the system’s equations [5] will be used for control design, with the unknown disturbance terms \( \Delta F \) and \( \Delta C \) considered as constant vectors.

3. Problem formulation of pipeline following by visual servoing

Assume that the AUV is equipped with an Inertial Measurement Unit (IMU), a Doppler Velocity Log (DVL) and a monocular camera. The IMU provides measurements of the angular velocity \( \Omega \) and an approximate of the gravity direction \( \mathbf{R}^T \mathbf{e}_3 \) (i.e., roll and pitch angles), whereas the DVL measures the translational velocity \( \mathbf{V} \). The visual features considered are the pipeline borders assumed to be parallel to each other (see Fig. 2). Assume that the curvature of the pipeline is negligible so that the pipeline direction \( \mathbf{u} \) in the inertial frame is approximatively constant. The inertial frame is chosen such that \( \mathbf{u} \in \text{span}(\mathbf{e}_1, \mathbf{e}_3) \).

Figure 2: Geometrical basis of the pipeline-following visual servo control problem

Provided that the observed borders of the pipeline are parallel, their Plücker coordinates \( \mathbf{h}_i, \mathbf{U} \in S^2 \times S^2 \), \( i = [1, 2] \), expressed in the camera frame \( \mathbf{C} \), can be measured directly from the image features [Mahony and Hamel (2005)] as follows (see Fig. 2)

\[
\begin{align*}
\mathbf{h}_i &= \pm \frac{\mathbf{y}^i_1 \times \mathbf{y}^i_2}{|\mathbf{y}^i_1 \times \mathbf{y}^i_2|} \\
\mathbf{U} &= \pm \frac{\mathbf{h}_{1i} \times \mathbf{h}_{2i}}{|\mathbf{h}_{1i} \times \mathbf{h}_{2i}|}
\end{align*}
\]
(6)

where \( \mathbf{y}^i_1 \) and \( \mathbf{y}^i_2 \) are the metric pixel coordinates (i.e. 3D coordinates of a point divided by its depth) of points belonging to the observed borderline \( i \) w.r.t. the optical center of the image. The direction of the pipeline \( \mathbf{U} \) expressed in the camera frame is specified up to a sign that should be assigned by the operator. The proposed visual servo control is based on the centroid vector computed from visual features [6] as follows (see Fig. 3)

\[
\mathbf{q} = \mathbf{h}_1 + \mathbf{h}_2
\]

One verifies that \( \mathbf{h}_i \) is also equal to \( \mathbf{h}_i = \frac{\mathbf{U}}{|\mathbf{U}|} \) where \( \mathbf{H}_i = \mathbf{P}_i \times \mathbf{U} \) and \( \mathbf{P}_i \) is the vector of coordinates, expressed in \( \mathbf{C} \), of the closest point \( P_i \) on the line to the origin of the camera frame \( \mathbf{C} \).

The kinematics of \( \mathbf{U}, \mathbf{P}_i, \) and \( \mathbf{H}_i, \) with \( i = 1, 2 \), are inherited from the camera motion relative to the observed pipeline. Since \( \mathbf{u} \) is constant by assumption, one obtains [Mahony and Hamel (2005)]

\[
\begin{align*}
\dot{\mathbf{U}} &= -\mathbf{U} \times \mathbf{X} \\
\dot{\mathbf{P}}_l &= -\mathbf{U} \times \mathbf{P}_l - \pi \mathbf{V}_C \\
\dot{\mathbf{H}}_i &= -\mathbf{U} \times \mathbf{H}_i - \mathbf{V}_C \times \mathbf{U}
\end{align*}
\]
(7)

From these equations one derives the dynamics of the centroid vector \( \mathbf{q} \) as

\[
\mathbf{q} = -\mathbf{U} \times \mathbf{q} - Q(V_C \times U)
\]
(8)
Proof. Since \( u \in \text{span}(e_1, e_3) \) and under assumption that \( U \rightarrow e_1 \) and \( e_2 R^T e_3 \rightarrow 0 \), one deduces \( \sin \phi \rightarrow 0, \sin \theta \rightarrow \sin \beta, \sin \psi \rightarrow 0 \), which locally ensures the convergence of \( (\phi, \theta, \psi) \) to \((0, \beta, 0)\). \( \square \)

Define the visual position-like error as

\[
\delta_1 \triangleq q - \pi_U q^*.
\]

Note that \( \delta_1 \) is orthogonal to \( U \), which is an important property to be exploited in the outer-loop control design.

The control objective consists of stabilizing the lateral and vertical positions of the pipeline w.r.t. the camera frame to the borderline of index \( i \), i.e. \( |H_i| = |P_i| \). Since these distances are not known when using a monocular camera, the matrix \( Q \) is not known either for control design.

Let \( q^* \) be the reference value of \( q \). Control action must ensure the asymptotic stabilization of \( q \) about \( q^* \). The latter is typically chosen constant and parallel to \( e_2 \) (i.e. \( q^* = 0 \)) and \( q^* = |q^*| e_2 \), leading implicitly to stabilize the AUV in the middle of the pipeline at the desired relative distance encoded in \( |q^*| \).

Remark 1. It is worth providing a physical interpretation on the magnitude of \( q^* \). It is verified that \( |q^*| = 2 \cos \alpha^* \) with \( \alpha^* = \arctan(l_p/(2d^*)) \), where \( l_p \) and \( d^* \) are respectively the width of the pipeline and the distance between the camera and the pipeline associated to \( q^* \). This means that the norm of \( q^* \) must be chosen smaller than 2 (i.e. \( |q^*| < 2 \)) and that the more it gets close to 2 the larger the distance \( d^* \) (i.e., \( \lim_{|q^*| \rightarrow 2} d^* = +\infty \)).

The control objective consists of stabilizing the roll, pitch and yaw angles locally asymptotically converge to \((\theta, \beta, 0)\) to \((0, \beta, 0)\) to stabilize the vector \( U \) about \((\theta, \beta, 0)\) to \((0, \beta, 0)\). Additionally, the pitch angle must asymptotically converge to \( \beta \) about \((0, \beta, 0)\).

4. Control design

The following cascade inner-outer loop control architecture (illustrated by Fig. 4) is adopted.

- The inner-loop control defines the force and torque control vectors \( F_r \) and \( \Gamma_r \) that ensure the asymptotic stabilization of \((V_r, \Omega_r) \) about \((V_r, \Omega_r)\), where the reference velocities \( V_r \) and \( \Omega_r \) are determined by the outer-loop control.

- The outer-loop control is specifically designed from the image features to define the desired velocity setpoint \( V_r \) and \( \Omega_r \) as well as their derivative to fulfill the main objective of stabilizing \((\delta_1, U, V)\) about \((0, e_1, v_r e_1)\).

4.1. Outer-loop control design

For a fully-actuated AUV with force and torque control inputs, it is not too difficult to design an inner-loop controller that ensures the global asymptotic stability and local exponential stability of the equilibrium \((V, \Omega) = (V_r, \Omega_r)\), provided that the derivatives of \( V_r \) and \( \Omega_r \) are computable by the controller. Let us thus postpone the inner-loop control design and focus on the outer-loop control design, which is the main contribution of this paper.

The outer-loop control design is directly based on the features measured in the image plane, with the objective of stabilizing \((\delta_1, U, V)\) about \((0, e_1, v_r e_1)\).

From (7), (8) and (9) one verifies that the dynamics of \( \delta_1 \) satisfies

\[
\dot{\delta}_1 = -\Omega \times q - Q(V_C \times U) + (U U^T + U U^T) q^* \\
= -\Omega \times (\delta_1 + \pi_U q^*) - Q(V_C \times U) + (-\Omega, U U^T + U U^T \Omega_r) q^* \\
= -\Omega \times \delta_1 - \pi_U (\Omega \times q^* - Q(V_C \times U)) \tag{10}
\]

Now in order to provide the reader with some control insights, the kinematic case using the velocities \( V \) and \( \Omega \) as control inputs is investigated.

Lemma 2. (Kinematic Control) The kinematic controller

\[
\begin{align*}
\Omega &= k_u e_1 \times U \\
V &= U \times \delta_1 + v_r U + \Omega \times r_C \tag{11}
\end{align*}
\]

with \( k_u \) a positive gain, globally asymptotically stabilize \( U \) about \( \pm e_1 \) and \( \delta_1 \) about zero. Additionally, the velocities \( \Omega \) and \( V \) converge to zero and \( v_r U \), respectively.
Proof. Consider the following positive storage function:

$$S_1 \triangleq 1 - U^T e_1$$  \hspace{1cm} (12)$$

From (7), (11a) and (12) one verifies that the derivative of $S_1$ satisfies

$$\dot{S}_1 = -U^T \Omega e_1 = -\Omega^T (e_1 \times U) = -k_u (U_2^3 + U_2^3)$$

Provided that $\Omega$ is considered as control input, system (7) is autonomous. Therefore, the application of LaSalle’s principle ensures the convergence of $S_1$ and thus, of $U_2$ and $U_3$ to zero. This implies that $U$ converges to either $e_1$ or $-e_1$. The convergence of $\Omega$ to zero then follows from its definition (11a).

From (11b) one deduces $V_C = k_\Omega U \times \delta_1 + v_r U$. Now, consider the second positive storage function $S_2 \triangleq \frac{1}{2} \delta_1^T \delta_1$. Using (10), and the expression of $V_C$ previously obtained and the orthogonality of $\delta_1$ to $U$, one deduces

$$\dot{S}_2 = -\delta_1^T \pi_U (\Omega \times q^*) - \delta_1^T \Omega V_C (U \times \Omega)$$

$$= -\delta_1^T \pi_U (\Omega \times q^*) + k_\delta^2 \delta_1^T \Omega (U \times \delta_1)$$

$$= -\delta_1^T \pi_U (\Omega \times q^*) - k_\delta \delta_1^T \Omega \delta_1$$  \hspace{1cm} (13)$$

Since the matrix $Q$ is positive definite and the vanishing term $\pi_U (\Omega \times q^*)$ remains bounded for all time, one deduces from (18) and the definition of $S_2$ that $\delta_1$ and $\delta_2$, converge to zero. Finally, the convergence of $\delta_1$ and $\Omega$ to zero ensure the convergence of $V$ to $v_r U$.

Remark 2. Since $V$ and $\Omega$ are not the physical control variables, some modifications should be made. In view of Lemma 2 one may define the reference velocities $V_r$ and $\Omega_r$, as in the right hand side of Eqs. (11a)–(11b) and apply an inner-loop control to ensure that $V$ and $\Omega$ converge to $V_r$ and $\Omega_r$. However, since the derivative of $V_r$ is not computable by the inner-loop control due to the term $\delta_1$ involved in the expression (11b) and, subsequently, the stability of the equilibrium $(V_r, \Omega_r)$ is no longer guaranteed unconditionally. More precisely, in order to compute the derivative of $V_r$, one needs to know the derivative of $\delta_1$. Nevertheless, in view of the expression (11b) of $\delta_1$, it is not computable by the controller due to the unknown matrix $Q$.

As mentioned previously, the knowledge of the derivative terms $V_r$ and $\Omega_r$, is required by the inner-loop controller. To this purpose, the reference velocities $V_r$ and $\Omega_r$ are defined as (compared to (11a)–(11b))

$$\Omega_r \triangleq k_u e_1 \times U - k_u e_1 (e_1^T R^T e_1)$$  \hspace{1cm} (14a)$$

$$V_r \triangleq [e_1]_x + v_r e_1 + \Omega_r \times r_c$$  \hspace{1cm} (14b)$$

where $k_u$ and $k_\Omega$ are some positive gains, and the augmented variable $\delta_2 \in \mathbb{R}^2$ is the solution to the augmented system:

$$\dot{\delta}_2 = K_1 \delta_1 - K_2 \delta_2, \quad \delta_2(0) = 0$$  \hspace{1cm} (15)$$

with $\delta_0 \in \mathbb{R}^2$ the initial condition, some positive diagonal matrices $K_1 = \text{diag}(k_{11}, k_{12}), K_2 = \text{diag}(k_{21}, k_{22}) \in \mathbb{R}^{2 \times 2}$, and $\delta_1 \triangleq [\delta_{12}, \delta_{11}]^T \in \mathbb{R}^2$ the vector of the two last components of $\delta_1$. Since the derivative of $U$ and $\delta_2$, given by (7) and (15) respectively, can be computed by the controller and since $\delta_2$ can be obtained by integration of Eq. (15), it is straightforward to verify that $V_r$ and $\Omega_r$ are also computable by the controller.

**Proposition 1.** Let the reference velocities $V_r$ and $\Omega_r$ be specified by the outer-loop controller as in Eqs. (14a)–(14b). Apply any inner-loop controller that ensures the global asymptotic stability and local exponential stability of the equilibrium $(V_C, \Omega_r) = (V_C, \Omega_r)$. Let $\lambda^\inf Q, \lambda^\sup Q > 0$ denote the supremum of the largest eigenvalue and the infimum of the smallest eigenvalue of the symmetric positive definite matrix $Q \triangleq [Q_{22}, Q_{23}, Q_{33}] \in \mathbb{R}^{2 \times 2}$. Let $\gamma_Q$ denote the bound of $Q$. Assume that the control gains $K_1$ and $K_2$ involved in Eqs. (14b) and (15) satisfy

$$k_{1\text{max}} \leq \frac{1}{e_1^T \lambda^\inf Q, \lambda^\sup Q e_1^T} < \frac{1}{e_1^T \gamma_Q^2} k_{2\text{max}}$$  \hspace{1cm} (16)$$

with some positive number $\varepsilon$ and

$$k_{1\text{max}} \triangleq \max(k_{11}, k_{12}), \quad k_{1\text{min}} \triangleq \min(k_{11}, k_{12})$$

$$k_{2\text{max}} \triangleq \max(k_{21}, k_{22}), \quad k_{2\text{min}} \triangleq \min(k_{21}, k_{22})$$

Then, $U$ is stabilized about $e_1$, and $\delta_1$ and $\delta_2$ are stabilized about zero. Additionally, $(V, \Omega)$ asymptotically converge to $(0, v_r U)$.

Proof. As a consequence of the inner-loop control, the velocity errors $\dot{V} \triangleq \dot{V} - V$, and $\dot{\Omega} \triangleq \dot{\Omega} - \Omega$, converge to zero.

First, the convergence of $U_2$ and $U_3$ to zero is studied. Consider the storage function $S_1$ defined by (12). One verifies that

$$\dot{S}_1 = \Omega^T (e_1 \times U) = (\Omega + \Omega)^T (e_1 \times U) = -k_u U_2^3 - k_u U_3^3 + e_S_1$$  \hspace{1cm} (17)$$

with $e_S_1 \triangleq \Omega^T (e_1 \times U)$ a vanishing term. The application of Barbalat’s lemma (see Khalil (2002)) then ensures the convergence of $U_2$ and $U_3$ to zero, which implies that $U$ converge to either $e_1$ or $-e_1$.

Now the convergence of $\Omega$, to zero is studied. Consider the storage function $S_3 \triangleq 1 - e_1^T R e_1$. One verifies that

$$\dot{S}_3 = -(\Omega + \Omega)^T (e_1 \times R e_1)$$

$$= -k_u (e_1^T R e_1)^T (e_1 \times R e_1) + e_{S_3}$$

$$= -k_u (e_1^T R e_1)^2 + e_{S_3}$$  \hspace{1cm} (18)$$

with $e_{S_3} \triangleq -k_u (e_1 \times R e_1)^T (e_1 \times R e_1) - \bar{\delta}_1 (e_1 \times R e_1)$ a vanishing term. From there the application of Barbalat’s lemma ensures the convergence of $e_1^T R e_1$ to zero. One then easily deduces the convergence of $\Omega$ and $\Omega$ to zero using its definition (14a).

The convergence of $\delta_1$ and $\delta_2$ to zero is now investigated. Using (10), (14b) and (15) one deduces

$$\delta_1 = Q(U \times v_r) + e_{s_1} = -Q e_1 \begin{bmatrix} 0 \\ \bar{\delta}_2 \end{bmatrix} - Q e_1 \begin{bmatrix} 0 \\ \bar{\delta}_2 \end{bmatrix} + e_{s_1}$$  \hspace{1cm} (19)$$
with \( \epsilon_\delta \triangleq -\Omega_\delta \delta_\delta - \pi_k_\delta (\Omega \times q^*) + Q(U \times (\mathbf{\bar{V}} + \Omega \times r_C)) \) a vanishing term. One notes that the first component of \( \delta_1 \) converges to zero by construction since \( \delta_1 \) is orthogonal to \( U \).

One deduces the following zero-dynamics, corresponding to \( \epsilon_\delta = 0 \):

\[
\begin{align*}
\dot{\delta}_1 &= -Q\delta_2 \\
\dot{\delta}_2 &= K_1\delta_1 - K_2\delta_2
\end{align*}
\]  

(20)

By application of singular perturbation theory \cite{Khalil2002}, in order to prove the convergence of \( \delta_1 \) and \( \delta_2 \) to zero, it suffices to prove the exponential stability of the equilibrium \( (\delta_1, \delta_2) = (0, 0) \) of the zero-dynamics (20).

Consider the following Lyapunov function candidate:

\[
\bar{L} = \frac{1 + \epsilon}{2} \delta_1^T \bar{Q}^{-1} \delta_1 + \frac{1}{2} \delta_2^T \bar{K}_1 \bar{K}_1^{-1} \delta_2 - \epsilon \delta_1^T \bar{K}_2^{-1} \bar{K}_1 \delta_2
\]

\[
\geq \frac{1 + \epsilon}{2} \delta_1^T \bar{Q}^{-1} \delta_1 + \frac{1}{2} \bar{k}_{\min} |\delta_2|^2 - \epsilon \bar{k}_{\min} |\delta_1|^2
\]

(21)

with some positive number \( \epsilon \). One verifies from (20) and (21) that

\[
\dot{\bar{L}} = \frac{1 + \epsilon}{2} \delta_1^T \bar{Q}^{-1} \delta_1 - \epsilon \delta_1^T \bar{K}_2^{-1} \bar{K}_1 \delta_1
\]

\[
+ \epsilon \delta_2^T \bar{K}_2^{-1} \bar{Q} \delta_2
\]

\[
\leq - \left( \frac{\epsilon \bar{k}_{\min}}{\bar{k}_{\max}} - \frac{(1 + \epsilon) \bar{Q}_{\min}}{2(\bar{Q}_{\min}^2)} \right) |\delta_1|^2 - \left( \frac{\epsilon \bar{Q}_{\sup}}{\bar{k}_{\min}} - \frac{\epsilon \bar{Q}}{\bar{k}_{\min}} \right) |\delta_2|^2
\]

From there, using condition (16) one deduces that \( \bar{L} \) is positive definite and \( \bar{L} \) negative definite. The exponential convergence of \( \delta_1 \) and \( \delta_2 \) to zero then directly follows, allowing one to conclude the proof. \( \square \)

Remark 3. The outer-loop controller (14)-(15) has been improved w.r.t. the one proposed in our prior work \cite{Krupinski2017}. In particular, the use of diagonal gain matrices \( K_1 \) and \( K_2 \) (justified by rigourous stability analysis) instead of the corresponding scalar gains used in \cite{Krupinski2017} allows one to locally decouple the outer-loop system (in first order approximations) into 3 independent subsystems corresponding to yaw, vertical and lateral dynamics, with the flexibility of independent gain tuning. This allows one to limit the influence of yaw and lateral dynamics on the transient behaviour of the vertical motion and thus avoid large overshoot in the altitude and limit the risk of collision with the ocean floor.

An additional modification to the outer-loop controller (14)-(15) in order to reduce the influence of a large initial yaw error on the transient translational motion can be made by replacing the expression (14b) by the following equation:

\[
V_r = \mu([U_\delta](e_1)_e) \begin{bmatrix} 0 \\ \delta_2 \end{bmatrix} + \mu([U_\delta](e_\bar{v}_r) e_1 + \Omega_r \times r_C
\]

(22)

where \( \mu(\cdot) \) is a differentiable monotonic increasing function defined in \([0, 1]\) satisfying \( \mu(0) = 0 \) and \( \mu(1) = 1 \). For instance, \( \mu(x) = \varepsilon + (1 - \varepsilon)|x|^{2^\mu}, \) with \( 0 < \varepsilon < 1 \) a small number and \( n \) a large integer, in the simulation section.

The introduction of the function \( \mu(\cdot) \) allows one to prioritize the stabilization of \( U \) over the stabilization of other control variables (i.e. \( \delta_1 \) and \( V_r \)). It can be easily shown that this modification does not affect the stability results stated in Proposition 1. In fact, from the proof of Proposition 1 one notes that the outer-loop control (14a) of \( \Omega \) ensures the convergence of \( U \) to \( \pm e_1 \) independently from any expression of \( V_r \). Therefore, \( \mu(\cdot) \) ultimately converges to 1, which implies that (22) is ultimately equivalent to (14b) and hence the associated stability analysis can proceed identically.

4.2. Recall on inner-loop control design

Although the inner-loop control design for a fully-actuated AUV is not too challenging and is not the main preoccupation of this paper, it is recalled here for completeness.

The inner-loop control objective can be stated as the stabilization of \( (\mathbf{V}, \Omega) \) about zero, with \( \mathbf{V} \triangleq \mathbf{V} - V_r \) and \( \tilde{\Omega} \triangleq \Omega - \Omega_r \). Then, using (5c) and (5d) one obtains the following coupled error dynamics:

\[
\mathbf{\dot{V}} + D^T \tilde{\Omega} = (M \mathbf{V} + D^T \Omega) \tilde{\Omega} + (\tilde{\Omega}M + \delta \tilde{\Omega}) \Omega_r
\]

\[
+ F_{\text{sh}} + \bar{F}_{\text{sh}} + F_r + F_r
\]

\[
(23a)
\]

\[
J \mathbf{\dot{\tilde{\Omega}}} + D^T \tilde{\Omega} = (J \Omega + D^T \Omega) \tilde{\Omega} + (\tilde{\Omega}J + D^T \tilde{\Omega}) V_r
\]

\[
+ \bar{G}_r + \bar{G}_r + G_r + G_r
\]

(23b)

where \( F_r \), and \( G_r \), the feedforward terms that should be compensated for by the controller, are defined by:

\[
F_r \triangleq -MV_r - D^T \Omega_r + (MV_r + D^T \Omega_r) \Omega_r
\]

\[
G_r \triangleq -\tilde{\Omega} \mathbf{V}_r - D \Omega_r + (\tilde{\Omega} \Omega_r + D \Omega_r) \Omega_r + (MV_r + D^T \Omega_r) \Omega_r
\]

For the sake of completeness, the following proposition are recalled from our prior work \cite{Krupinski2017}.

Proposition 2. (see \cite{Krupinski2017}, Pro.3) Consider the system dynamics (23a)-(23b) and apply the following controller:

\[
\begin{align*}
F_r &= -K_r \mathbf{V} - K_r \mathbf{Z}_r - (\mathbf{M} \mathbf{V} + \mathbf{D} \tilde{\Omega}) \times \Omega_r \\
+ \mathbf{D} \tilde{\Omega} \times \Omega_r + \mathbf{M} \tilde{\Omega} \times \mathbf{V}_r - F_{\text{sh}} - \bar{F}_{\text{sh}} - F_r \\
G_r &= -K_r \tilde{\Omega} - K_r \mathbf{Z}_r - (\mathbf{J} \tilde{\Omega}) \Omega_r - (\mathbf{D} \tilde{\Omega}) \times \mathbf{V}_r
\end{align*}
\]

(24)

with \( K_r, K_r, K_r \), some positive diagonal 3 \times 3 gain matrices, \( \mathbf{Z}_r \triangleq \int_0^t \mathbf{V}(s) \mathbf{d}s, \mathbf{z}_0 \triangleq \int_0^t \tilde{\Omega}(s) \mathbf{d}s \), and

\[
\begin{align*}
\bar{F}_r &= -(D V_r + \mathbf{V} \mathbf{D}_{\text{sh}}) \mathbf{V}_r \\
\bar{G}_r &= -(\mathbf{D} \mathbf{V}_r + \mathbf{O} \mathbf{D}_{\text{sh}}) \mathbf{V}_r
\end{align*}
\]

(25)

Assume that the disturbance terms \( \Delta r \) and \( \Delta \tilde{\Omega} \) are constant and that \( \mathbf{V}, \Omega \), and their derivative are bounded. Then, the equilibrium of the controlled system \((\mathbf{V}, \Omega, \mathbf{Z}_r, \mathbf{z}_0) \) is globally asymptotically stable (GAS) and locally exponentially stable (LES).
The proof of this proposition given in [Krupinski et al., 2017] consists in showing that the time-derivative of the following Lyapunov function candidate is negative semi-definite:

\[
\mathcal{L}_{\text{inner}} \triangleq \frac{1}{2} \mathbf{W}^T \mathbf{M}_f \dot{\mathbf{W}} + \frac{1}{2} (\mathbf{z}_v - \mathbf{K}_f^{-1} \mathbf{A}_f)^T \mathbf{K}_f \mathbf{A}_f (\mathbf{z}_v - \mathbf{K}_f^{-1} \mathbf{A}_f) \\
+ \frac{1}{2} (\mathbf{z}_\Omega - \mathbf{K}_\Omega^{-1} \mathbf{A}_\Omega)^T \mathbf{K}_\Omega (\mathbf{z}_\Omega - \mathbf{K}_\Omega^{-1} \mathbf{A}_\Omega)
\]

with \( \mathbf{M}_f > 0 \) given by (1) and \( \mathbf{W} \triangleq (\mathbf{V}^T, \mathbf{\Omega}^T)^T \).

In practice the roll motion may not be actuated by conception (i.e. \( \Gamma_{\perp} \equiv 0 \)) like the Girona-500 AUV used for experiment validations and is, thus, left passively stabilized by restoring and dissipative roll moments. A solution to such a situation can be easily adapted as proposed in [Krupinski et al., 2017] Sec.IV.A.

5. Validation results

5.1. Comparative simulation results

This section illustrates the performance of the proposed approach compared to the state-of-the-art IBVS approach proposed in [Rives and Borrelly, 1997] via a realistic simulation of a fully-actuated AUV model. Simulations have been carried out using Matlab/Simulink. The physical parameters of the simulated fully-actuated AUV given in Tab. 1 are those of the Girona-500 AUV along with rough estimates of added mass, added inertia and damping coefficients.

Table 1: Specifications of the simulated AUV.

For all comparisons, the value of \( \mathbf{q}^* \) is \( \mathbf{q}^* = 1.9901 \mathbf{e}_2 \) that corresponds to the situation where the vehicle moves at 1[m] above and in the middle of the pipeline having a diameter of 0.2[m]. The desired speed \( v_r \) along the pipeline is 1[m/s].

In order to make fair and simple comparisons between the two approaches, it is considered that the current velocity is equal to zero and that the estimated parameters of the AUV’s model are equal to the real values. In the sequel, it is called:

**Controller 1 – the proposed controller:** The control gains of the inner-loop and outer-loop are tuned based on the classical pole placement technique. For the inner-loop, two triple negative real poles equal to \(-2\) and \(-4\) are chosen for the linearized closed-loop system (29) for the particular case where \( \nu_r \equiv \nu_f \equiv 0 \). The gain matrices \( \mathbf{K}_V, \mathbf{K}_\nu, \mathbf{K}_\nu^V \) and \( \mathbf{K}_\Omega \) are given by

- \( \mathbf{K}_V = \text{diag}(330.8, 922.1, 960), \mathbf{K}_\nu^V = \mathbf{0} \)
- \( \mathbf{K}_\nu = \text{diag}(351.8, 438.7, 280), \mathbf{K}_\Omega = \mathbf{0} \)

For the outer-loop, negative real poles \((-2.6, -1.2)\) for the subsystem of vertical motion, and negative real double pole \(-2.5\) for the subsystem of the lateral motion are used.

Figure 5: Comparison 1 (left resp. right) column for controller 1 (resp. 2)) for small initial errors \( \mathbf{p}_e(0) = [0, 1.5, -3.5]^T \) and \( \mathbf{R}(0) = \mathbf{R}_{180} \equiv \mathbf{R}_{360} \equiv \mathbf{R}_{720} \) (from top to bottom): AUV position and attitude (Euler angles) vs. time, visual error vs. time.

Figure 6: Comparison 2 (left resp. right) column for controller 1 (resp. 2)) for medium initial errors \( \mathbf{p}_e(0) = [0, 3, -6]^T \) and \( \mathbf{R}(0) = \mathbf{R}_{120} \equiv \mathbf{R}_{240} \equiv \mathbf{R}_{360} \) (from top to bottom): AUV position and attitude (Euler angles) vs. time, visual error vs. time.
on the linear approximation of system \(^\text{1}\) at the equilibrium. The gains are given by

- \( \kappa_\rho = 6, \kappa_\theta = 0.5, \)
- \( \mathbf{K}_1 = \text{diag}(41.36, 3.31), \mathbf{K}_2 = \text{diag}(3.8, 5), \)
- \( \mu(\|U_1\|) = \varepsilon + (1 - \varepsilon)\|U_1\|^2 + \varepsilon = 0.05, n = 5. \)

- **Controller 2** – the IBVS controller proposed in [Rives and Borrelly (1997)]: It is based on classical visual servoing approach applied to lines, corresponding to the projection of the borderlines of the pipe onto image features. In this case, the visual errors are given by the difference of the polar coordinates \( [p_1, \theta_1, p_2, \theta_2]^\top \) of the current lines and the associated values \( [p_1^\star, \theta_1^\star, p_2^\star, \theta_2^\star]^\top \) of the desired lines. As discussed in [Rives and Borrelly (1997)] two lines are not enough to ensure a global minimum, roll stabilization to zero is needed independently. Therefore, the term \( \kappa_\rho \mathbf{e}_3^\top (\mathbf{e}_3 \times \mathbf{R}^\top \mathbf{e}_3) \) is added in the computation of the control torques to help the roll stabilization to zero. The gains involved in this controller are \( k = 0.3, \mu = 5/3, \beta = 1, \kappa_\omega = 0.5. \)

Extensive simulations have been carried out using the two controllers. Three simulations are reported next that correspond to three different initial conditions (i.e. small, medium and large errors in translations and rotations).

- In the first simulation (see Fig. 5), both the controllers exhibit a quite good behaviour. The pose (i.e. position and orientation) quickly converges to the desired values while the visual errors converge smoothly to zero.

- In the second simulation (see Fig. 6), the convergence of the visual errors to zero and of the pose to the desired values is still achieved for both controllers. However, one observes some oscillations in the attitude’s time evolution of Controller 2 in contrast to the smooth convergence without overshoot in the attitude of Controller 1.

- When the initial errors are very large especially in roll angle (see Fig. 7), Controller 2 becomes unstable while Controller 1 still ensures a very satisfactory performance (i.e. fast convergence without oscillations). The poor performance of Controller 1 in this case is not surprising since its design and stability analysis are only established on local basis.

The reported simulations show some net improvements in terms of convergence domain and smooth transient response of the proposed IBVS approach w.r.t. to the IBVS approach proposed in [Rives and Borrelly (1997)].

5.2. Experimental results

The Girona-500 AUV developed by the Underwater Vision and Robotics Center (Girona, Spain) [Ribas et al. (2012)] (see Fig. 8) has been used to perform experimental validations. The AUV is composed of an aluminium frame to support three torpedo-shaped hulls. Its dimensions are \( 1 \times 1 \times 1.5 \text{[m]} \) in height, width and length, and its weight is approximately \( 160 \text{[kg]} \) in air. The vehicle is actuated by two horizontal thrusters for yaw and surge actuations, two vertical thrusters for heave and pitch actuations and one lateral thruster for sway actuation. Roll motion is left passively stabilized (i.e. \( \Gamma_{c1} \equiv 0 \)). The mounted sensor suite of the AUV consists of an IMU, a DVL and a downward-looking camera providing images at about 5-7 Hz.

In order to emulate an inspection of an underwater pipeline, a pipeline mockup, whose diameter is approximately \( 0.2 \text{[m]} \), is placed in a pool (see Fig. 9). ROS middleware is used to transfer images from camera in low-bandwidth compressed formats. A bridge between ROS images and OpenCV is also used to obtain in real time the parameters of the pipeline borders.

The control gains and other parameters involved in the computation of the control inputs are given by

- \( \mathbf{K}_V = \text{diag}(145.4, 418.5, 480), \mathbf{K}_{V} = 0.1 \mathbf{K}_V \)
- \( \mathbf{K}_\Omega = \text{diag}(96.9, 124.7, 70), \mathbf{K}_\Omega = 0.1 \mathbf{K}_\Omega \)
- \( \kappa_\rho = 0.5, \kappa_\omega = 1 \)
- \( \mathbf{K}_1 = \text{diag}(2.65, 0.3), \mathbf{K}_2 = \text{diag}(0.9, 1.5) \)

\(^1\)The notation of gains \( k, \mu, \beta \) is adopted in [Rives and Borrelly (1997)].
\[ q^* = 1.9901e_2, \upsilon_2 = 0.15[m/s] \]
\[ \mathbf{r}_C = [0.5, 0, 0.5]^T[m] \]

The estimated summed inertia (i.e., inertia + added inertia) and summed mass (i.e., mass + added mass) are those in Tab. 1 in which the off-diagonal elements are neglected. Finally, the damping force and torque vectors (i.e. \( \mathbf{F}_d \) and \( \mathbf{\Gamma}_d \)) are also neglected. In the following, experimental results will be reported. Due to space limitation, only brief but representative parts of total results are presented. However, the reader is invited to view a video clip showing the whole experiment (see multimedia attachment) at https://youtu.be/jPHlJ2CYHLI.

Experimental results are reported in Figs. 9–12. They correspond to the multimedia attachment. Fig. 10 shows the practical convergence of \( \mathbf{U} \) near to \( e_1 \) whereas the vector of image feature \( \mathbf{q} \) converges near to the desired value. The time evolution of the visual error \( \delta_1 \) is given in Fig. 11. One observes that the convergence is obtained in a short period with quite satisfactory behaviour. Fig. 9 presents an overview of current images taken during the AUV’s motion where the lines obtained from image processing using Hough algorithm are displayed in red.

Finally, Fig. 12 shows the control force and torque vectors computed from the inner-loop. Since the Girona-500 AUV is positively buoyant, the third component of the control force vector practically converges to 75[N]. The longitudinal component \( F_{c1} \) practically converges to the force needed to counteract the drag force corresponding to the forward velocity about 0.15[m/s] along the pipeline. The lateral component \( F_{c2} \) also converges near to a non-null value (\( \approx 6[N] \)) which can be explained by the fact that the vehicle is not perfectly aligned with the pipeline and thus resulting in non-negligible lateral drag. As for the control torque, the second component \( \mathbf{\Gamma}_{c2} \) converges near to \( -7[N.m] \), allowing to maintain the vehicle horizontally. This non-null value is due to the fact that the vector \( \overrightarrow{BG} \) connecting...
the CoB and CoM is not aligned with the vertical basis vector \( e^v_2 \). From this figure one also observes some isolated spikes in the control forces and torques. This is intrinsically due to the fact that for some “security” reason the Girona-500 AUV randomly sent some impulsive additive signals to the inner-loop control independently from the proposed controller. However, these “incidental” random and short signals did not affect the overall performance of the proposed approach, showing the robustness of the latter.

6. Conclusions

A nonlinear visual servo control for pipeline following for fully-actuated AUVs has been proposed. The originality of the proposed approach lies in exploiting the full system dynamics in control design. The controller directly uses the image features as feedback information without exploiting the relative pose of the vehicle with respect to the environment. Since practically no knowledge of the Cartesian world is mandatory, the implementation, especially in uncertain or changing scenes is greatly simplified. Rigorous stability analysis for closed-loop systems has been given. The theoretical analysis has been complemented by comparative simulation results between the proposed control approach and an existing IBVS controller and also by experimental validations that shows the effectiveness of the proposed control scheme, even when the system parameters are not known precisely. As perspectives, it would be interesting to improve the proposed approach in the case where DVL measurements become inaccurate or missing, due to low velocity or in close proximity to man-made infrastructures.
