Abstract

The field of high performance computing (HPC) has provided a wide array of strategies for supplying additional computing power to the goal of reducing the total "clock time" required to complete large scale analyses. These strategies range from the development of higher performance hardware to the assembly of large networks of commodity computers. However, for the non-computational scientist wishing to utilize these services, usable software remains elusive. Here we present a software design and implementation of a tool, Grid Wizard Enterprise (GWE; http://www.gridwizardenterprise.org/), aimed at providing a solution to the particular problem of the adoption of advanced grid technologies by biomedical researchers. GWE provides an intuitive environment and tools that bridge this gulf between the researcher and current grid technologies allowing them to run inter-independent computational processes faster by brokering their execution across a virtual grid of computational resources with a minimum of user intervention. The GWE architecture has been designed in close collaboration with biomedical researchers and supports the majority of every-day tasks performed by computational scientists in the fields of computational biology and medical image analysis.

1 Introduction

Research in the computational sciences seems to proceed, roughly speaking, in distinct phases. As an initial idea for a computational protocol is refined, a researcher will iteratively debug and improve applications on a small amount of handpicked data, tweaking parameters and inspecting output for correctness. Once the idea returns plausible results and can be considered publication-worthy, the program gets run on more and more data, often involving a new round of debugging as new classes of pathological inputs are discovered. During this phase, the computational protocol undergoes systematic characterization: for what parameter ranges does it return valid results? Can any immediate conclusions or further hypotheses be derived from running on publicly available data? Finally, once the computational protocol is ready to be released to the scientific community, a researcher must decide how to distribute the code.

It is a lucky coincidence that the research process falls into the already useful class of embarrassingly parallel problems, that is to say, resource-intensive computational problems that can be broken into independent subunits that can run in parallel. A researcher who faces such a problem must deal with a number of tedious issues: how to determine what work needs to be done and how it should be broken into meaningful units (workload definition); how to assign individual work units to resources (application scheduling[1,3]); how to run and monitor executables (grid execution; e.g. Globus[2]); and how to deal with system-related and program-related failures (failure detection). As an example, current application scheduling frameworks (e.g. Condor[1], SGE[3]) would appear to provide the end user with an easy to use platform to broker the execution of his processes, however, unless his processes are extremely straightforward and trivial, the end user faces a daunting challenge. Most real application scheduling requests require the resolution of issues that, even in the presence of a powerful resource manager, have to be resolved by the end user: uploading the data to be processed to the cluster (localization); submit all processes to compute nodes (queue jobs in resource managers); monitor processes execution progress (real time and querying on demand); send / receive custom alert notifications (certain interesting conditions reached such as a percentage of processes completed execution); failover and recovery from cluster and environment related problems; failover and recovery from processes related problems; gathering and compilation of processing results; uploading result data to the storage resource of your choice; cleaning up the original and result data from the cluster data storage resource.

Though each of these problems can be solved in a straightforward way, the combined solutions to all of them leads to a maintenance problem, interferes with distribution, and presents an additional barrier to a scientist trying to investigate a particular problem. Two different solutions have evolved, as a way to bridge this gap: users gathering a considerable level of technical knowledge, which takes time and effort away from their actual domain problems; and the creation, (by technically savvy users and/or IT departments), of highly customized scripts and applications tailored to specific parallelization problems. Both these avenues don't provide the broader community of biomedical researchers with the ability to easily harness the growing number of clustered computational resources available to them. It is our view that a researcher expert in a particular scientific discipline should not need to also become an expert in grid computing in order to produce an application that uses grid technology. It is also our observation that the bulk of computational scientists do not have at their disposal dedicated programmers and system administrators to plan, install, configure, and maintain customized scripts or a complex heterogeneous network of computers.

To reflect these needs we have designed a system, Grid Wizard Enterprise (GWE) that facilitates the above considerations, which we derived based partly on our own experiences performing computational science in bioinformatics and partly on observing others doing the same. It is important to note that GWE is not meant to be another grid middleware package, rather, it is meant to be a large-scale job launching and management tool that bridges the gulf between the biomedical researcher and current grid middleware by:

- Providing the researcher with the ability to easily configure the heterogeneous clustered/grid resources that they have access to.
- Allowing a researcher to easily specify large parametric computational jobs using the same general syntax as is used in the command line invocation of the analysis algorithms (e.g. see P2EL in Section 4) or through integration with community developed biomedical applications (e.g. see Slicer in Section 5).
- Managing the most common house keeping tasks required to ensure end-to-end success of a computation thereby relieving the researcher of this burden.

2 Grid Wizard Enterprise (GWE)

GWE is a distributed enterprise system (Figure 1) that was designed to be a practical solution for end users to easily and effectively parallelize and broker the execution of their inter-independent processes on clustered or grid environments they have access to. This system provides a solution for the issues previously mentioned in Section 1 and with a high degree of modularity which allows third parties to extend and customize the GWE system. In order to lower the barrier for use by the typical biomedical researcher, the only requirements the system has over the environment it would be running on are to have available java 1.5 or higher and operate over a SSH enabled network.

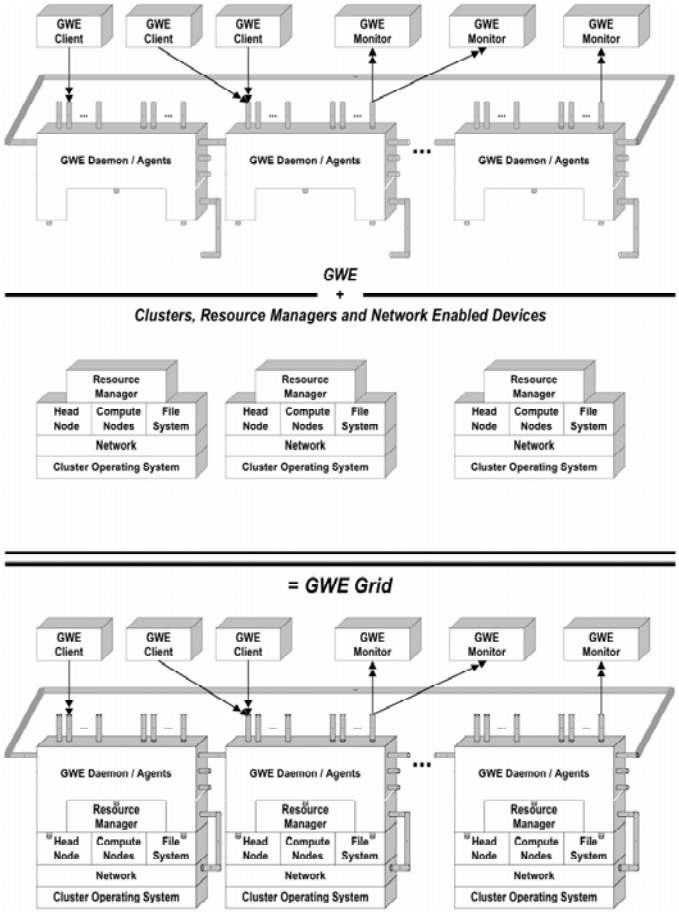

Figure 1: GWE Grid

2.1 Distributed System

From a user's perspective, GWE is composed of two subsystems. The first is the GWE client – the system running on end users machines to communicate with a 'GWE Grid' in order to query the execution status of previously submitted requests and submit new ones. This client can be access through the command line or integrated within a biomedical application.

The second is the GWE daemon – the system(s) running on clusters' head node to serve as a listener for end user requests, as a job dispatcher and as a monitor for the respective cluster. In addition, GWE daemons can communicate with one another when a user has requested a computation to be executed on multiple clusters. Typically, end users would connect to a particular 'GWE daemon' (running on a host on a reachable TCP/IP based network) using a 'GWE client'. A GWE client's configuration consists of: the list of clusters that compose the user's accessible grid resources, SSH authentication information of all the networked resources to be accessed (clusters, file systems, etc) and locations of applications to auto-deploy.

GWE daemons are easily deployed through an automated process in the GWE client distribution and can be installed by any user with a valid SSH account on a cluster head node. At runtime, GWE daemons will silently spawn low level 'agent type' sub-systems, which are scheduled to run on the compute nodes (one 'agent' per allocated compute node) by the local cluster's resource manager. These 'agents' will be in charge of the actual execution of the processes, monitoring status/progress/results and reporting back to the respective "daemon". A GWE daemons' configuration consists of multiple behavioral parameters. Among the most important are the ones used for its 'compute node allocation policy', such as queue size (maximum number of compute nodes allocated at any given time), "hijack" timeout (maximum time a compute node can remain allocated with active jobs before "releasing" its controlling agent) and "idle" timeout (maximum time a compute node can remain allocated with nothing to do before "releasing" its controlling agent).

2.2 Architecture & Design

All GWE subsystems have been architected as a set of independent modules and frameworks, glued declaratively using the 'Spring' application framework. Such modules have been designed with a robust and scalable infrastructure and with multiple levels of abstraction to provide a high degree of extensibility.

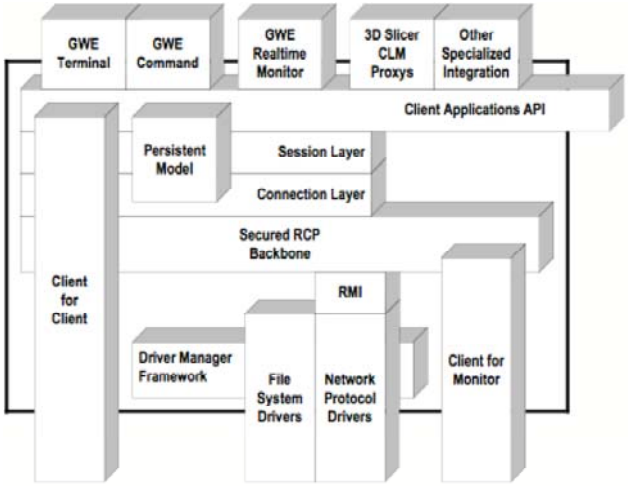

Figure 2: GWE Client Architecture

One of the most common extensible modules is the "GWE Client API" (Figure 2); used to build GWE client applications or empower applications with GWE client capabilities. Currently there are a few GWE client applications built using this API and they will be reviewed in more detail later in this paper. Internally this API contains many extensible sub-modules most of which have been further developed to reduce the effort required to add/change functionality. An example of this is the "abstract job descriptor" component; which can be extended to support languages other than P2EL, or even workflows with inter-dependent jobs.

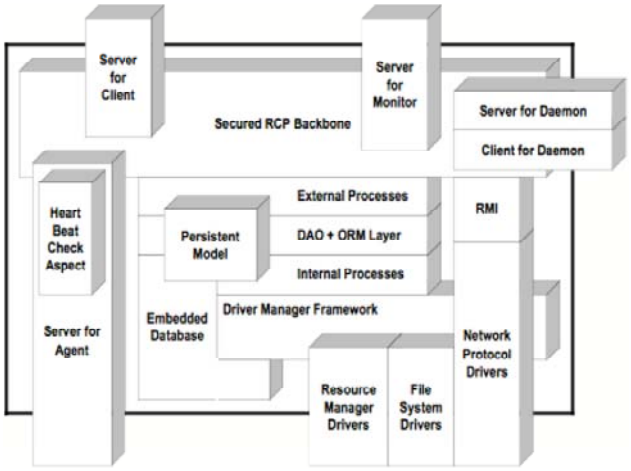

Figure 3: GWE Daemon Architecture

Finally, one set of extensible modules, which are a part of both the client and daemon (Figure 3), that deserve a special mention are the 'grid related resource drivers'. These drivers provide GWE with means to support new types of file systems, network protocols and cluster resource managers (which are auto detected per cluster when a GWE daemon is deployed). GWE comes out of the box with drivers to support the following 'resources': File Systems such as Local, HTTP and SFTP; Network Protocols such as Local and SSH; and Resource Managers such as Condor, SGE and PBS. GWE daemons include other robust enterprise level features such as highly multithreaded services to avoid wait cycles and achieve maximum performance; embedded database to persist operational data (users, orders, jobs, clusters, etc) and automatic failover and recovery from cluster, environment and process specific related problems.

However, the GWE system was designed to allow any biomedical researcher to easily access their available compute resources with tools they normally utilize: the command line, SSH and domain specific applications. Therefore, the GWE inter subsystem communications infrastructure has been architected as a secured RPC backbone using a Java RMI network tunneled over SSH. This tunneling infrastructure consists of a framework, which transparently injects a series of hooks (socket proxy, heartbeat emitters and heartbeat checkers) into the communications using interceptors and AOP (aspect oriented programming).

3 Usage and Integration with External Applications

The following section details GWE based solutions for the testing of a medical imaging algorithm through GWE. It is a common scenario for researchers to fine-tune an algorithm by running it over the same data set with different values for its algorithmic parameters (large scale parameter exploration). It is also a common scenario for researchers to have large set of files they want to process using the same behavioral parameters. The example we are going to explore in this section is a combination of both cases.

3.1 Setup

All GWE clients described below have the "GWE Client API Module" bundle installed (or pre-installed) under a specific path (by simply unbundling it there), and the GWE_HOME environmental variable set to such specific path. Under "$GWE_HOME/conf", one finds GWE's configuration information; which is customized to fit the computing environment:

- **gwe-grid.xml**. Contains information about the clusters to be used (head node addresses mainly).
- **gwe-auth.xml**. Contain the user's authentication information to access the networked resources including cluster head nodes, remote file systems, etc.
- **gwe-apps.xml**. Contain information about the applications the user wants pre-installed in clusters before executing his/her orders (bundle locations, bundle architecture, reference id, etc.)

3.2 P2EL (Process Parallelization Execution Language)

In order to provide the semantics for users to easily and effectively describe a group of process invocations including all related parallelization meta-instructions, a simple but powerful language (P2EL) has been designed for GWE (and an appropriate interpreter built into it). This language is a combination of pseudo bash and pseudo VLT (Velocity Template Language). This language has semantics to define:

- **Process Invocation Templates** are Bash like, meta-templates containing iteration variables references (substitution expressions). These templates will be used to generate all the process invocations of the respective P2EL statement.
- **Substitution Expressions** are "bash like" variable expressions embedded in the template to be replaced by the corresponding value-space.
- **Iteration Variables** are variables associated with a value-space set, which when applied to a process invocation template, generate a collection of processes invocations. This construct gets its values explicitly or implicitly through numerous ways including runtime value resolving functions.
- **System Variables** are variables associated with a system and/or contextual property resolved at runtime for a specific job (e.g. the iteration number generated by GWE and user home).
- **Staging Files Instructions and Locations** instruct how to stage remote files into the context of process invocation (before executing it) and how to stage files produced by the process invocation out to selected destination locations.

3.2.1 Medical Imaging Algorithm Example

Problem

Slicer's "BSpline Deformable Registration" is a medical imaging algorithm; which resamples a "moving" image using a "fixed" one and a set of algorithmic parameters. The following is an example of this command submitted from a regular OS shell for a single invocation:

```
Slicer3 --launch /usr/Slicer3/lib/Slicer3/Plugins/BSplineDeformableRegistration
--iterations 10 --gridSize 5 --histogrambins 20 --spatialsamples 500
--maximumDeformation 1 --default 0
```

```
--resampledmovingfilename out.nrrd
f.nrrd m.nrrd
```

It is obvious the immediate complexity a researcher faces when trying to process multiple "moving" images against a "fixed" one using multiple parameter set values (download moving images, iterate over them and over the parameter values, check for temporary storage space, save resulting images in temporary storage space, upload resulting images, persist execution logs, etc).

GWE Solution

Using GWE, a researcher only needs to submit a workload description (utilizing a P2EL command); which has the same general form as the associated OS shell command (above) using the generic GWE command lines clients (or an equivalent workload description using other tools such as GSlicer3 described later in this paper). The following P2EL command illustrates a real use case; which are equivalent to 125 actual analyses per moving file found in the specified location:

```
${ITER}=[10..50||10] ${HIST}=[20..100||020] ${SAMP}=[500..5000||1000]
${MOV}=f:expand(sftp://srcHost/srcDir/moving-*.nrrd)
Slicer3 --launch /usr/Slicer3/lib/Slicer3/Plugins/BSplineDeformableRegistration
--iterations ${ITER} --gridSize 5 --histogrambins ${HIST} --spatialsamples ${SAMP}
--maximumDeformation 1 --default 0
--resampledmovingfilename f:out(sftp://destHost/destDir/out-f:sys(ITER_ID).nrrd)
f:in(f.nrrd,http://otherSrcHost/otherSrcDir/fixed.nrrd?view=co) f:in(m.nrrd,${MOV})
```

GWE Solution Details

This command instructs GWE to run Slicer's "BSpline Deformable Registration" for each moving image that matches the wildcard pattern 'sftp://srcHost/srcDir/moving-*.nrrd' against the fixed image 'http://otherSrcHost/otherSrcDir/fixed.nrrd?view=co', for each possible combination of values for: iterations (ITER = 10, 20, 30, 40 and 50), histograms (HIST = 020, 040, 060, 080 and 100) and samples (SAMP = 0500, 1500, 2500, 3500 and 4500). The output is saved under the remote directory 'sftp://destHost/destDir/' with the name 'out-[ITER_ID].nrrd', where '[ITER_ID]' is the unique auto-generated identifier of the job. Transparently, GWE carries on many implicit multithreaded tasks such as:

- Determines user authentication information, and requests the user to login if SSH keys are not utilized, to the remote file system in order to be able to query it.
- Queries the remote file system to resolve the files that match the pattern used in variable ${MOV}.
- Expands the command into a set of inter-independent jobs to be processed in parallel using every possible combination of the ${ITER}, ${HIST}, ${SAMP} and ${MOV}. Each one of those jobs is a Slicer "BSpline Deformable Registration" invocation.
- Creates a virtual file system in the home directory of the user submitting the command to store downloaded files, resulting files, files to upload, log files, etc.
- When a compute node is assigned to process a job, the GWE agent scheduled on that node by the cluster's scheduling framework: downloads a copy of its requiring files to the virtual file system cache (if a copy is not already downloaded) and creates a working copy of it for the particular job; creates a placeholder file in the virtual file system for the files to upload (f:out); uploads the necessary files when finished processing; updates job status, save logs and results in DB, cleans up virtual file system; and logs for each of the processes executed (job) are saved in GWE's internal DB, so researchers can retrieve them, and output files are stored in the locations specified.

The previous task breakdown is an overview of what happens within a GWE system, however, we feel it is a good a description detailed enough to provide the reader with a feeling of the high level tasks GWE carries out on their behalf in order to get the processes executed.

3.3 GWE Generic Client Applications

The above example details the use of GWE through its generic client implementation. Two such clients exist. The GWE Terminal is a console application which keeps a live connection to a particular GWE daemon and allows the user to interactively query status information and submit requests. This application is ideal when the user is going to interact for a while with a GWE daemon. Alternatively, GWE Commands are Java command line applications meant to give the end user the capabilities to access a particular daemon, issue a particular command and exit. Usage of these applications is slightly more expensive than using the GWE Terminal since a brand new network connection has to be established every time they are invoked. However, they provide quick command line access to a GWE daemon and a basic API for integrating GWE requests programmatically through scripts.

3.4 GWE-Slicer3 Integration (GWE Slicer3 Client Application)

3.4.1 Slicer3

The National Alliance for Medical Image Computation's (NA-MIC) Slicer3[4] (http://slicer.org/) is a "free, open source software package for visualization and image analysis. Slicer's capabilities include: interactive visualization of images, manual editing, fusion and co-registering of data, automatic segmentation, analysis of diffuse tensor imaging data, and visualization of tracking information for image-guided procedures. Some of the core functionality that enables these applications include the capability to save and restore scenes using a format called MRML, a plug-in architecture to interface to external programs including ITK, a sophisticated statistical classification environment based on the EM algorithm, capabilities for rigid and non-rigid data fusion and registration, and processing of DTI MRI data."[5]

3.4.2 Objective

Researchers often encounter the need to run medical imaging algorithms over a large set of values to be permutated for different arguments (see P2EL example above), from algorithm calibration parameters to sets of images (i.e. sets of images utilized for testing an algorithm to large collections of images collected as part of a study that are ready to be processed). Executing all these processes on a single computer may take a really long time depending on the amount of processes and the number of file transfers. In addition, the gathering of results requires a lot of manual work and is highly prone to error.

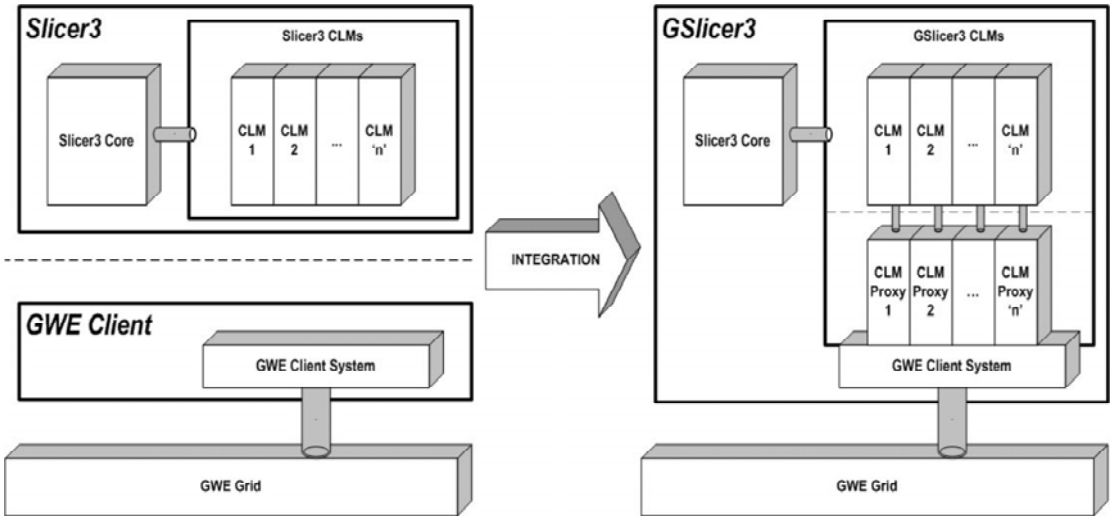

Figure 4: Slicer3 /GSlicer3 Architecture Comparison

Slicer3, provides an infrastructure to easily integrate medical imaging applications ('modules') as self-describing pluggable components. Taking advantage of this feature, GWE can be generically integrated with Slicer3 to allow researchers to execute their set of processes in parallel across a distributed environment while handling all the 'side' tasks that otherwise would have to be done manually.

3.4.3 Design

Slicer3 modules execute as regular command line applications, which must conform to a straightforward, proprietary specification. This specification requires these modules to "self describe" when invoked with the predefined reactor argument of '--xml' which results in the generation of a proprietary XML descriptor stating the module's arguments metadata (flags, types of values, label, etc). Slicer3 uses this metadata to dynamically render an appropriate UI to collect the values for each argument and to generate the module command line invocation when needed to run the module per a user's request.

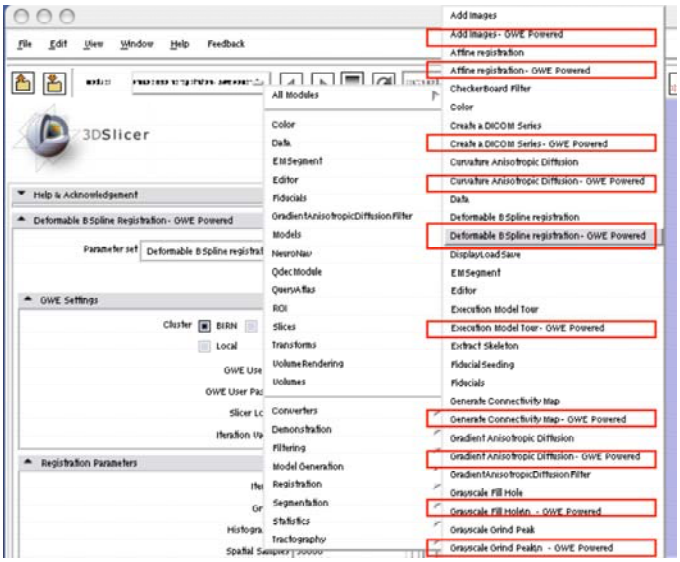

Figure 5: Grid enabled modules

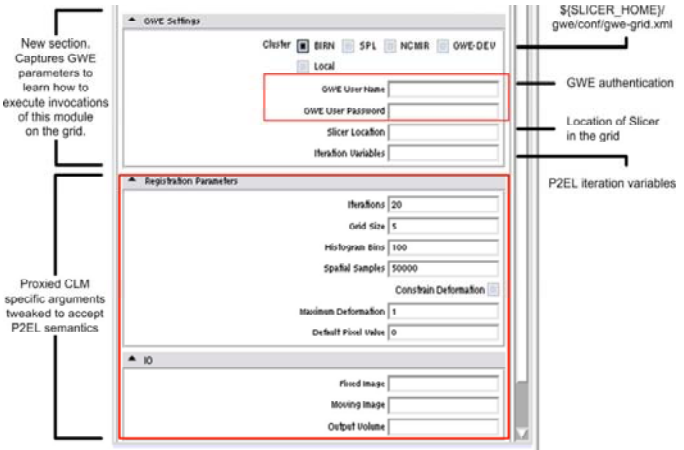
The integration effort consists of installing the 'GWE Client API' inside a Slicer3 installation and generating new Slicer3 modules (Figure 5), one for each 'regular' Slicer3 module intended to be leveraged with grid computing capabilities. These new modules are called "GWE CLMPs" (command line module proxies) and the user can utilize them when trying to run a set of processes in a distributed grid environment, otherwise they can work as usual with the 'regular' versions. This effort includes a 'bundling' utility, which installs GWE inside a Slicer3 distribution, introspects it to discover all its pluggable modules and dynamically generates a corresponding GWE CLMP for each of them. The end result is the grid-enabled version of Slicer3, which we will refer to as GSlicer3.

When GSlicer3 is launched, the end user will notice that (in the available modules menu) for every regular module, there is another named exactly the same with the additional suffix of " – GWE Powered" (Figure 6). These correspond to the CLMPs modules that have been auto generated by the 'bundling' utility. GWE CLMPs are intelligent agents, which conform to the Slicer3 module specification responding as required to the predefined reactors and have an explicit association to their corresponding 'regular' version module. The proxied module creates its "self description" by retrieving the "self description" of the associated 'regular' module and enhances them with the appropriate GWE related descriptions. Using these dynamically generated "self descriptions", GSlicer3 is able to render a suitable UI (Figure 6) to capture the

Figure 6: Grid enabled module UI



necessary arguments to execute invocations of the associated module via GWE. Also, such UIs support P2EL semantics so value added functions (file transfers, wildcard resolution, etc) are all available. A CLMP is in essence a "GWE client application" which at runtime will carry on the following tasks:

- Retrieve, add and modify the XML tags of their proxied CLM's XML descriptor in order to add arguments, add fields to set, and capture specific GWE parameters and P2EL value types.
- Generate a GWE order with the P2EL command corresponding to the user's input appropriately translated to the selected cluster resource (e.g. Slicer3 location, user home directory, etc).
- Install a customized Slicer result parser to the GWE order.
- Submit the GWE order created to the selected cluster resource, over the secured RPC GWE network.
- Monitor, in real time, the execution progress of the localized proxied CLM invocations (from the GWE order) on the selected cluster. This real time monitoring is also performed over the secured RPC GWE network.
- Keep track of the CLMP progress as a ratio of the number of proxied CLMs invocations already executed divided by the total amount of proxied CLMs invocations associated with the GWE order submitted.
- Notify Slicer3 of this progress using Slicer3 XML based progress API (<filter-XXX > tags sent to the standard output of the CLMP).

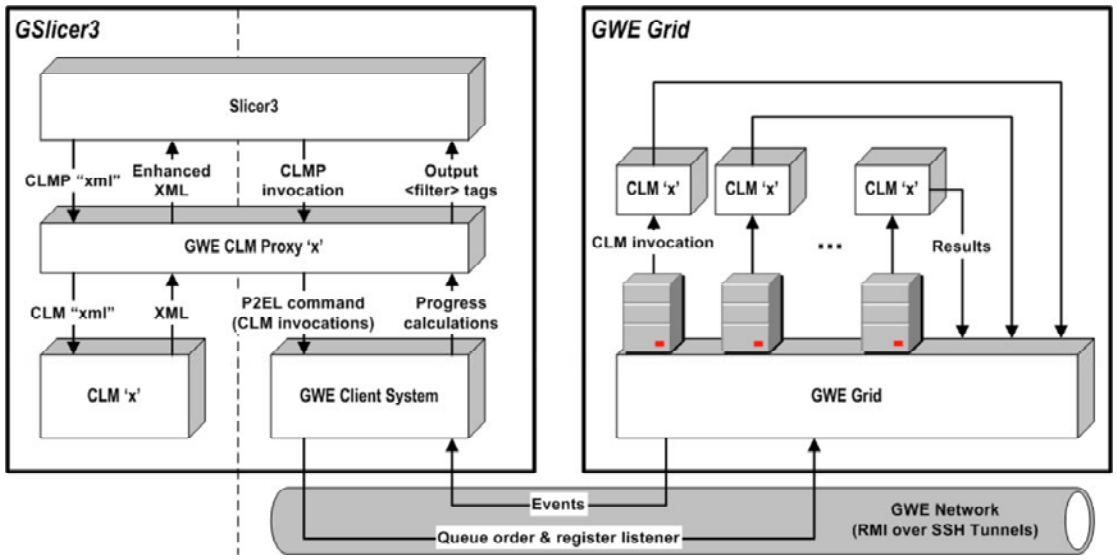


Figure 7: GSlicer3 Execution Flow

This integration effort provides a generalized, easy to use grid computing enabled interface to all Slicer3 CLMs that are "Standard Execution Model" compliant.

3.4.4 Usage

As described in the previous section, every GWE CLMP has an associated UI where the user can input values for its parameters (Figure 6). This UI supports the input of parameters expected by its associated 'regular' version module and/or P2EL semantics (see P2EL section). Using these values, the GWE CLMP generates a P2EL command and submits it to the selected cluster (Figure 7). The selection of the cluster is done by selecting one of the possible clusters, defined in the gwe-grid.xml file (Section 3.1), shown as radio buttons on top of the UI. For example, using the "BSpline Deformable Registration" CLMP a user can submit the order described in section 4.2 via the GSlicer3 user interface.

4 Future Work

This system is currently in its 4th alpha release. The current project plan is to release a new version every 6 weeks and release the first feature complete beta version in the beginning of 2009. In order to reach the beta release, the product is going through extended testing with biomedical researchers to elicit usability and functional requirements. As a result of this testing the following features are being finalized (a-d), implemented (e-h) and tested:

a. Application registry framework - provides capabilities to auto-deploy applications to running clusters on an as needed basis. Currently the Slicer3 integration described above assumes that Slicer3 is installed on the running clusters.
b. Multi-cluster module - provides true grid abstraction through the ability of GWE to distribute jobs to a specified set of clusters in a "daisy chain" configuration.
c. Array of iteration variables feature - provides the means to specify a set of values-sets to apply all at once as a single variable. For example: VAL_SET=[(0,10,20),(15,27,-3)] would create 1 permutation with the first set of 3 values and a second permutation with the second set.
d. Parametrical order behavioral logic - provides the means for end users to customize execution aspects of the jobs associated with an order, such as, job timeouts, launch mode, file system clean up policy, maximum concurrent jobs running, etc.
e. Alert notification module - provides the means for end users to specify job runtime conditions under which the system shall send notifications to customizable recipients (typically an email to a specified email address).
f. Job result parser framework - provides an infrastructure for the end user to create his/her own result parser to inject into a specific order so it can extract meaningful structured data out of the job results.
g. Additional grid related drivers for file system drivers (i.e. SRB, XCEDE based XML file catalogs, and GridFTP) and resource managers (e.g. Torque).
h. Portal client integration as JSR-168 portlets that can be deployed to any standards based portal container.
