ABSTRACT:
Aspect-Oriented Modeling (AOM) approaches propose to model reusable aspects, or cross-cutting concerns, that can be composed in different systems at a model or code level. Building complex systems with reusable aspects helps managing software complexity. But in general, reusability of an aspect is limited to a particular context. On the one hand, if the target model does not match the template point-to-point, the aspect cannot be applied. On the other hand, even when it is actually applied, it is woven into the target model always in the same way. In this paper, we point out the needs of variability in the AOM approaches and introduce seamless variability mechanisms in an existing AOM approach to improve reusability. Our aspects can fit various contexts and can be composed into the base model in different ways. Introducing variability into AOM approaches will turn standard aspects into highly reusable aspects.

Abstract. Aspect-Oriented Modeling (AOM) approaches propose to model reusable aspects, or cross-cutting concerns, that can be composed in different systems at a model or code level. Building complex systems with reusable aspects helps managing software complexity. But in general, reusability of an aspect is limited to a particular context. On the one hand, if the target model does not match the template point-to-point, the aspect cannot be applied. On the other hand, even when it is actually applied, it is woven into the target model always in the same way. In this paper, we point out the needs of variability in the AOM approaches and introduce soundless variability mechanisms in an existing AOM approach to improve reusability. Our aspects can fit various contexts and can be composed into the base model in different ways. Introducing variability into AOM approaches will turn standard aspects into highly reusable aspects.

1 Introduction

The Aspect Oriented Software Development (AOSD) paradigm first appeared at the code level a decade ago \cite{7} with the most famous AOP language AspectJ \cite{6}. The aspect paradigm offers a new way to construct complex systems by composing crosscutting concerns with the base system. In the earlier stages of the software life-cycle, several Aspect-Oriented Modeling approaches (AOM) already exist \cite{4, 13, 1, 2}, with various levels of abstraction (requirement, design, architecture). In general, these approaches decrease the complexity of systems by composing models that represent the different concerns of the system (business, security, persistence …). To help developers saving time designing systems and therefore reduce the time-to-market of these systems, models should be reusable.

Currently, AOM approaches provide some means to design reusable and flexible aspects. But, reusability and flexibility are often limited. In general, they describe one possible variant of an aspect and propose one possible way to integrate it. For example, a designer cannot model a design pattern in its full genericity with these approaches: he can only model one specific implementation choice for this design pattern. Consequently, aspects are only reusable in
similar or very related contexts. In this paper, we argue that aspects must be
reusable in various contexts. Designing context independent aspects requires
seamless variability mechanisms for specifying the weaving, the pointcut expres-
sion, etc.... Such mechanisms will turn standard aspects into highly reusable
and flexible pieces of models.

The contribution of this paper is to point out the needs of variability in
the AOM approaches, to provide some mechanisms to support variability in one
particular AOM approach and to illustrate these new mechanisms on a concrete
example. To address variability in software development, Software product lines
(SPL) offer some mechanisms to support functional variability and to derive
products that match the user's needs. However, this variability only concerns
the software module specifications. In the case of AOM approaches, variability
should also be applied onto the composition mechanisms.

The remainder of this paper is organized as follows. Section 2 points out the
needs of variability in the AOM approaches with a motivating example. Section 3
presents an overview of an AOM approach. This approach is extended in the
section 4 to support variability mechanisms. Section 5 describes a metamodel
for this approach and the implementation of a modeling tool. Section 6 presents
related works and section 7 concludes and discusses future work.

2 Motivating example

To illustrate the needs of variability in the AOM approaches, we use the example
of a mobile phone device. Figure 1 shows a simplified class diagram presenting
the main functionalities of an accountancy package for a mobile phone.

![Class Diagram](image)

**Fig. 1.** A Simplified class diagram of the mobile phone

When the user is calling (resp. is called by) someone, the *HistoryCall* class
creates a new outgoing (resp. incoming) call and saves the duration. The class
*GUI* can display its local variable *time* which is initialized when switching on
the phone. The class *Clock* only contains a variable *time* which is incremented
every minute.

---

4 see Software Product Line Conferences : http://www.splc.net
2.1 Matching variability

Two optional requirements, **total calls** and **total outgoing calls**, can be added to our mobile phone in order to compute the total duration of the (outgoing) calls. We will use the Counter pattern [10] to realize these two requirements.

![Counter pattern diagram]

*Fig. 2. The Counter pattern realizing the total calls requirement*

In most of the AOM approaches [2, 10, 13], a template specifies the model elements of the concern that have to be bound with target model elements. Reusability is then limited to iso-structural target models because if the structure does not match the template point-to-point, the aspect cannot be applied.

Figure 2 shows the Counter pattern composition into the mobile phone model. In order to realize the **total calls** requirement, we use the existing `HistoryCall` and `Call` classes to respectively act as `Counter` and `Element`. We now want to realize the **total outgoing calls** requirement but in this case, no class can act as `Counter` in the mobile phone model. Instead of modifying the base model by creating a new class acting as `Counter`, it would be more efficient that the Counter pattern automatically introduces all the missing elements, but this is not possible with classic AOM approaches [2, 10, 13]. The weaving process of the aspect upon the base system has to vary depending on the bindings.

2.2 Adaptation variability

One optional requirement, **display time**, can be added in order to display and update the time every minute, when the internal clock is updated. The Observer pattern will realize this requirement, notifying the GUI (Observer) that the Clock (Subject) has been updated.

In most of the AOM approaches [2, 10, 13], aspects are composed into the target model using one composition rule at a time, offering poor flexibility. Depending on the context, it would be very useful to easily switch between different composition rules. In the context of embedded systems it may be preferable to reduce the number of classes because of memory limitations, and completely merge the aspect while in some other cases, it may be preferable to compose the aspect by inheritance in order to improve readability. Figure 3 illustrates another composition rule where `Subject` is merged into `Clock` whereas `GUI` inherits from `Observer`. 

*Fig. 3. The Observer pattern realizing the display time requirement*
This motivating example has shown the need for variability in two contexts i.e. matching and adaptation. There is also a need for functional variability e.g. how to design many versions of the Counter pattern (total or average for example). Since Software Product Line approaches [14] can help modeling this kind of variability, we do not cover them in this paper.

3 An AOM approach Overview

The approach which is presented in this paper is only one among many possible approaches for addressing AOM [3,10]. It focuses on providing capabilities for concerns (functional or extra-functional) to be reused. In this context, the expressiveness of the concern modeling is not a primary objective. For example, contrary to other non aspect-oriented approaches like [14], we do not offer more capabilities for expressing the variability of concerns than the one provided by the underlying metamodel used for the concern specification. The approach called SMART Adapters had been applied first to Java programs [8] and more recently to EMF models. Its key concepts are concerns, adapters, adaptations and adaptation target. The main idea is the following: each concern identified as reusable should go with an adapter which specifies a composition protocol, that is a set of adaptations and adaptation targets describing how the concern should be composed with other concerns when it is reused. This protocol will guide the designer to identify the specific parts for reuse when composing a reusable concern into a target concern.

We propose to explain this approach through the reuse of the Observer design pattern. First we define its composition protocol (see Figure 4). For better readability, we use a concrete textual syntax in order to specify this composition protocol. Details in the concrete syntax are not important and the syntax might be slightly modified in the future.

Let us now detail this example illustrated in Figure 4. Line 01 specifies the concern to be reused. The adapter called ObserverAdapter describes its composition protocol (Line 02). When the composition protocol is defined the concern(s) that may reuse it are not known so that we do not know the classes corresponding to the objects acting as subjects and those acting as observers. The only thing that we may assume is that there are classes that act as observers and subjects. They are represented by the two abstract targets of type class: observerClass
and subjectClass (Lines 04 and 05). Each of these targets may be associated to one or several classes at composition time.

```java
01 concern designpatterns.observer
02 abstract adapter ObserverAdapter {
03   abstract Class target "class(es) representing an observer" : observerClass
04   abstract Class target "class(es) representing a subject" : subjectClass
05   abstract Method target "method(s) notifying changes" : notifyingMethod
06       require notifyingMethod in subjectClass.*
07   adaptation becomeObserver "Modify class to make it an observer" :
08       inherit Observer in observerClass
09   adaptation becomeSubject "Modify class in order to make it a subject" :
10       merge class subjectClass with Subject
11   adaptation introduceLink "introduce an association (subject to observer)" :
12       introduce Association observers (subjectClass -> observerClass)
13   adaptation notifyingObserver ""Altering notifyingMethods to tell observers about modifications"
14       extend method notifyingMethod(...) with after { changeValue(); }
15   abstract adaptation updateObserver "add an update facility to observers" :
16       introduce method public void update(subjectClass s) in observer
17       ... Protocol includes also object initialization, observers registration,...
18 }
```

**Fig. 4.** Snippet of the composition protocol for the Observer design pattern

Considering the design pattern Observer of Figure 3, any subject must inform an observer that its content has been modified by calling the method changeValue. For the same reasons that the classes mentioned above are not known the method(s) playing this role are also not known but they should exist and be declared in the subjectClass (Lines 06 and 07). To ensure that the call to changeValue is performed by the method(s) notifyingMethod, the composition protocol specifies an adaptation of type interception which adds this call at the end of the corresponding method(s) (Lines 18 to 20).

More generally this kind of adaptation deals with some actions to be taken when a classifier member (attributes, methods...) is accessed or called. These adaptations allow the designer to add behavior at the beginning, end or around some existing methods but also to add some treatment when an exception is triggered. For attributes, interception may occur when the attribute is read or modified.

Let us continue with our example. To be able to call changeValue or any other feature of class Subject, it is necessary to have access to it from within the classes corresponding to subjectClass. This means that we have to specify another adaptation. Two possibilities could be chosen: to merge all the features of class Subject into subjectClass, or to make subjectClass inherit from Subject. Here we choose an adaptation of type Merging (Lines 12 and 13).

Such adaptations deal mainly with packages, classifiers features and associations. Method merging is particularly interesting if there is a support for
describing the behavior (programming constructs in Kermeta [12], Sequence diagrams in UML, etc.). At present time merging policies are mainly execution of one method before the other; the handling of interlaced method bodies could be inspired by approaches like [9]. Merging classifiers is either straightforward (no conflict, name of features to be merged are identical, feature appear only in one of the classes, . . . ) or may need more information in order to relate the features of the classifiers that need to be merged [2, 13].

All these adaptations were dealing with the subjects. It is then necessary to address observers and to also insert class Observer at the right place(s) in the reusing concern. We chose here to inherit from it (Lines 99 and 10). Such adaptation is of type Introduction. It deals not only with superclass introduction as it is the case here but also with adding classifier members (new attributes or methods), as well as association. It is also possible to add a classifier invariant or a method assertion (Precondition or postcondition).

We use the same type of adaptation to insert the association between subject and observer classes as specified in the design pattern. Depending on the association to be introduced we may provide additional information. For example, in the current case the association is unidirectional from subjects to observers (Lines 15 and 16).

It only remains one thing to do: to add to the observerClass class(es) a method update (also an adaptation of type Introduction), that reacts to the changes made in the subject object. At this time we do not know the content of this feature because we do not know what the purpose of the reusing concern is. This is why the adaptation is abstract. The advantage to plan this adaptation in the composition protocol is to guide and control the reuse of the design pattern.

This composition protocol continues with the description of the initialization and the registration of observers but for space reasons we do not include it.

Let us suppose now that this concern is reused by the concern described in Figure 1 (Section 2) dealing with mobile phones. So we need to compose these two concerns. The information which is incomplete into the composition protocol (abstract targets and adaptations) is described into a concrete adapter ApplicationPhone which specializes the adapter ObserverAdapter as it is shown in Figure 5. Please note that, in this example, the insertion is in situ. It means that adaptations are performed within the concern applicationPhone. In some cases, it is better to make the composition ex situ that is to say to compose the two concerns into a new one.

In the above composition protocol (Figure 4) we made several assumptions about the reusing concern. For example, we suppose that the association does not yet exist between the classes GUI (the observer) and Clock (the subject). This is a drawback because if the composition does not deal with a concern which satisfies these assumptions, it will be impossible to reuse the composition protocol in another context. Thus, we reach the conclusion that we need to introduce some variability within the composition protocol. This is the purpose of section 4.
4 Extension to support variability

In Section 3 we proposed an overview of the SmartAdapters approach. We now consider the needs of variability pointed out in Section 2. Our objective in this section is to introduce matching and adaptation variability into the composition protocol in order to make it more reusable and as consequence to make the concern itself more reusable. SmartAdapters is a support for explaining our approach but we plan to address other AOM approaches. Variability mechanisms introduced are inspired by Software Product Lines approaches, especially [14].

Figure 6 shows what we should introduce in an adapter to better customize the composition protocol. In section 5 we will describe the metamodel containing the capabilities that are suggested here.

We may note first that adapter ObserverAdapter is now preceded by the keyword derivable (Line 02). This means that it may present several alternatives to implement the composition and may consider some adaptation targets or adaptations as optional. This adapter acts as a template where some information should be given in order to choose between possible variants or options.

A first possible customization is dealing with the insertion of the features provided by classes Subject and Observer. Depending on the reusing concern or more generally on the context of reuse, it may be interesting to have the choice between inheriting from those classes or merging their features into observerClass and subjectClass. In Figure 4 a choice is made a priori. In Figure 6, the choice is described by the Lines 09 to 24 through a clause Alternative Insertion Choices which specifies here two variants (more variants could be defined if needed!). A variant may contain several adaptation target declarations and adaptations. Implicitly this means that these targets and adaptations are dependent from each others.

Now, we can introduce the update method. If we merge the Subject and the Observer, we need to introduce the update method in the class where the Observer is merged i.e., observerClass (Lines 22 and 23). Subject is also merged in a target class, therefore the parameter of the update method has the type of this target class i.e. subjectClass. If the pattern is composed by inheritance, the update method is introduced in the Observer class itself, and the parameter has the type Subject (Lines 15 and 16). The update method is very related to

Fig. 5. Reuse of Design Pattern Observer for a mobile phone
the composition variant, so we integrate its introduction in the InsertionChoice alternative. Depending on the chosen composition variant, the right update method will be introduced. In both cases the contents of this method is not already known, that is why this method is abstract.

A second possible customization is related to the location of the call to method changeValue within notifyingMethod. It may be useful depending on the updating concern to notify the subject changes to observers either at the beginning or at the end of the execution of notifyingMethod. The corresponding variants are described by the Lines 22 to 31 through a second clause Alternative. Each variant corresponds to a unique adaptation of type Interception.

In figure 7 we extend this protocol to experiment the combination of optional and alternative clauses. We now address the association between observers and subjects (called observers in the design pattern of Figure 2). It is very likely that depending on the updating concern this association may already exist in it. In order to authorize the two situations we propose two variants (Lines 33 to 44). The first one assumes that the association exists in the updating concern and is identified by the target subjectObserverAssociation. In this case it may be possible to specify a renaming adaptation because nothing can ensure that it has the same association-end name in this concern. One may note that this

01 concerns designpattern.observer
02 derivable adapter ObserverAdapter {
03
04 abstract Class target "class(es) representing an observer" : observerClass
05 abstract Class target "class(es) representing a subject" : subjectClass
06 abstract Method target "method(s) notifying changes" : notifyingMethod
07 require notifyingMethod in subjectClass.
08
09 Alternative InsertionChoice "Choice between inheritance and merging" {
10 "Inheritance variant" :
11 adaptation becomeSubject "Modify class in order to make it a subject" :
12 inherit class Subject in subjectClass
13 adaptation becomeObserver "Modify class to make it an observer" :
14 inherit Observer in observerClass
15 abstract adaptation updateObserver "add an update facility to observers" : 
16 introduce method public void update(Subject s) in Observer
17 or else "Merging variant" :
18 adaptation becomeSubject "Modify class in order to make it a subject" :
19 merge class subjectClass with Subject
20 adaptation becomeObserver "Modify class to make it an observer" :
21 merge class observerClass with Observer
22 abstract adaptation updateObserver "add an update facility to observers" :
23 introduce method public void update(subjectClass s) in observerClass
24 }
25
26 Alternative NotificationTime "Choice of notification time" {
27 "Method beginning variant" :
28 adaptation notifyingObserver
29 " Alter notifyingMethods to tell observers about modification" :
30 extend method notifyingMethod( . ) with before { changeValue(); } 
31 or else " Method ending variant" :
32 adaptation notifyingObserver
33 " Alter notifyingMethods to tell observers about modification" :
34 extend method notifyingMethod( . ) with after { changeValue(); } 
35 } 
36 ... Protocol includes also subject initialization observers registration,...
37 }

Fig. 6. Composition protocol for the Observer with variability
optional adaptation may not exist if the second variant is selected. The second variant (case where the association does not exist) specifies an adaptation which introduces the association in the reusing concern.

01 concern designpattern.observer
02 derivable adapter ObserverAdapter {
03 ..
04
05 Alternative LinkSubjectObserver "’Access to observers may exist or not’" {
06 "Association exists":
07 abstract AssociationTarget "’association (observers to subject)’":
08 subjectObserverAssociation
09 is optional LinkModification "’Association may be renamed’":
10 abstract adaptation modifyLink "’modify association-end name’":
11 rename Association subjectObserverAssociation
12 or else "’Association does not exists’":
13 introduction association observers (subjectClass -> observerClass)
14 }
15 }
16 }
17 ...
18 }

Fig. 7. Options and matching variability

The example developed in Figures 6 and 7 especially illustrates the needs for optional parts and variant definitions. But the DSL that we use in this paper allows the designer to describe hierarchies of variants and options so that it implicitly defines dependency and mutual exclusion constraints. It also allows the designer to define flat variants and options in order to increase the number of potential combinations and consequently to improve the protocol reusability; in this case the constraints should be defined explicitly. Finally if we continue the description of the composition protocol as mentioned at the end of Figure 6 we may add constraints between the location of the initialization, the statements for creating and registering observers and the targets which are declared.

Now, we can compose the variable “Design Pattern Observer” into the mobile phone base model. In addition to the tasks described in Figure 5 it is necessary to select options and variants (adaptation targets and adaptations) which are suitable for the concern “mobile phones”. Of course the abstract adaptation targets and adaptations to concretize in the adapter ApplicationPhone depends on the variants and options which are selected (Figure 8).

The selection is made through a clause derive (Lines 05 to 08). No association can match the observers association in the target model, so the second variant of the alternative clause LinkSubjectObserver is selected to introduce this missing association. We also select the two variants associated to the alternative clauses InsertionChoices and NotificationTime. Finally, we have to concretize the update method, specifying that the GUI has to increment its variable time and refresh the screen. Concretizing abstract methods in a concrete adapter is close to the mechanism defined in the AOP approach of Hannemann et al. [5]. Mandatory targets and adaptations of Figure 6 are processed normally in the same way as it is done in Figure 5.

Figure 9 shows two types of composition i.e. merging and inheritance, in order to realize the display time requirement. Inheritance corresponds to the
adapter we have derived above, while **Merging** corresponds to another possible derivation provided by the protocol.

![Diagram](image)

**Fig. 9.** Two possible compositions of the Observer pattern

In the motivating example, we were not able to realize the **total outgoing calls** with the standard Counter pattern because the template approach was not flexible enough. We can now realize the **total calls** and the **total outgoing calls** requirements using the same Counter pattern. Indeed, the Counter pattern now can be applied either if the class acting as **Counter** is present or not in the base model. For space limitation, the derivable adapter and the concrete adapter are not shown but the principle is similar to the Observer protocol (Figures 6, 7 and 8).

Finally, it is interesting to note that introducing variability did not affect the guidance and the controls when reusing a derivable concern. On the contrary, the choices induced by the addition of variability is also controlled and guided thanks to the expressiveness of the composition protocol.
5 Metamodeling and Implementing AOM with Variability

This section proposes a metamodel of concerns that includes concepts for adapters and variability illustrated in sections 3 and 4. This metamodel aims at giving a precise formulation of concerns and make it possible their integration into modeling tools. Figure 10 shows an excerpt of the metamodel where concepts introduced to handle variability are identified with a circle at the upper left. The key concepts of the metamodel are concern, adapter, target and adaptation.

Fig. 10. Metamodel of SmartAdapter with variability

A reusable concern (class ReusableConcern) is associated to a package (class PackageEntity) which contains the concern description\(^5\) and its protocol of composition (class AbstractAdapter). Concerns are not always reusable (class Concern). For example the concern which describes the GUI of an application is rather specific and may not be reusable; such concerns do not have a composition protocol but could be composed with other concerns. A concern refers to as many concrete adapters (ConcreteAdapter) as there are concern to be integrated with it.

\(^5\) We assume that a concern is described by a package of classes similarly to a UML class diagram.
An adapter (class Adapter) is identified by a name and may inherit (i.e., specialize) from another adapter. An adapter may be abstract (class AbstractAdapter), concrete (class ConcreteAdapter) or derivable (class Derivable). Each adapter contains adaptations (class Adaptation) and adaptation targets (class TargetDeclaration). A derivable adapter is an abstract adapter which supports variability; it allows the designer to customize the set of adaptations or the set of adaptation targets by expressing options, alternatives, dependencies and exclusions. Such an adapter is not intended to be used directly for composing concerns but serves to derive an adapter. A derived adapter is obtained using the method resolve of class DerivableAdapter which takes a derivation (class Derivation) parameter to select the adaptations and the adaptation targets among the options and variants. This adapter may be concrete, abstract or derivable depending on what is resolved by the derivation parameter.

A target declaration (class TargetDeclaration) specifies an adaptation target that matches the entities on which the adaptations relies on. An adaptation target may identify just one required element (class AbstractTargetDeclaration) (like the observers or the subjects in the design pattern Observer) or be fully specified (class ConcreteTargetDeclaration) by referencing the real element (class, method, ...) to adapt.

An adaptation (class Adaptation) specifies the action to be taken for an element of the reusable concern when it is composed. The metamodel includes a hierarchy of adaptation classes that are typed according to the types of target entities (package, classifier, method, attributes and association) and reflect the four kinds of adaptation currently proposed: interceptions, introduction, merging and redefinitions. Figure 10 shows two of the adaptation classes used in the previous examples (class ClassMerging and class MethodIntroduction).

To be able to take into account several variants for the integration of the concern, the metamodel includes the concept of alternative entity (EntityAlternative). An alternative entity may refer to several adaptations or adaptation targets (see xor link) but only one will be selected at composition time.

Adaptations, adaptation targets and even alternatives can be optional in a derivable adapter, that is to say that they are planned in the composition protocol but they could be retained or not when the concern is composed with another one. Optional elements of a derivable adapter are referenced by its options link.

Practically several adaptations or adaptations targets may be described in a given variant or be declared as an optional block. For this purpose we propose a way to group those entities (class EntityConjunction).

Classes EntityDependency and MutualExclusion allows us to specify that an adaptation, an adaptation target or more generally a group of entities may not be selected (variant or option) with other ones or on the contrary must be selected if some others are selected.

The metamodel described above has been used to build a modeling tool integrated in the Eclipse environment. This tool currently provides two main functionalities: designing models of concerns and adapters; composing concerns from their models. This tool has been implemented using the Eclipse Modeling
Framework (EMF) and the Kermeta language [12]. We have exploited EMF to define a Ecore version of our metamodel, reusing the Ecore metamodel for the description of concerns. The Kermeta language has been exploited to extend the Ecore version of our metamodel with operational behavior. This behavior performs several tasks related to the design and composition of concerns: it checks the consistency of adapters, computes derived adapters and compose elements of concerns from a set of adaptations. At this time, we are investigating the design of a concrete textual syntax for our metamodel like the one used in the previous section and we plan to build the concrete syntax tool using a metamodel centric approach as [11].

6 Related work

There exists numerous AOM approaches but few of them support variability mechanisms at the composition level [4, 13, 1]. In [2], Clarke et al. model an aspect in a template package specifying the structure and the behavior of the aspect with a class diagram and sequence diagrams. The template is composed of model elements present in the concern’s class diagram and specifies the elements that have to be matched in the target model. There is no functional or matching variability mechanism. The composition relationship authorizes multiple bindings i.e. it is possible to match several target model elements to the same concern model element. Adaptation lacks variability: concerns are indeed always merged into the target model. Note that it is possible to generate AspectJ code to postpone the weaving at code level. Our adaptation protocol allows the designer to define different variants of how the concern will be integrated in the target model. All the variability mechanisms we have identified may be adapted to Thème.

Müller et al [10] also propose an approach to compose a reusable model expressed as a template package with an existing model. To express this composition, they introduce an apply operator that specifies the mapping between template parameters and elements of the target model. Their approach addresses variability at the composition level by giving the capacity to annotate the apply operator with different strategies such as "merge" or "view". Strategies are only provided to get different resulting models. Compared to our proposal, this solution does not offer any mechanism to express options and variants for the reusable model. It is also less flexible as it does not offer finer grain mechanisms to control how elements of reusable and target models must be composed.

France et al [13] have developed a systematic approach for composing class diagrams in which a default composition procedure based on name matching can be customized by user-defined composition directives. These directives constrain how class diagrams are composed. The framework automatically identifies conflicts between models that have to be composed and it solves them thanks to the composition directives. Contrary to Thème, composition directives address the weaving only from the structural point of view. They consider the composition as a model transformation. The variability can be addressed by designing several composition directives depending on the integration context. However, the definition of the composition directive would then become messy and error-prone. Besides, it is a symmetric AOM approach in which they do not differentiate be-
tween aspect model and base model. Consequently, they do not currently provide a pointcut language to manage the composition.

In [5], Hannemann et al. propose an AOP approach to implement design patterns with AspectJ. They propose up to seven different implementations for each design pattern. The only variability mechanism is the generalization relationship between an abstract aspect and an aspect. For example, the update method of the Observer is declared abstract in an abstract aspect and its contents will be specified in a concrete aspect. We also use this mechanism but the variability mechanisms we introduced allow a concern to be applied in multiple contexts whereas we would have to create a new aspect depending on the context with the Hannemann et al. approach. Option and variant notions do not exist, reducing the reusability of the aspects. Our concerns are adaptable and do not need modifications to be applied, but only customization. Introducing the same variability mechanisms at the code level could enhance the expressiveness of AOP language such as AspectJ.

7 Conclusion

In this work, we propose an approach for introducing variability in aspect-oriented modeling (AOM). To achieve this goal, two important parts of such an AOM approach were needed: A concern model and a weaver that support variability. In this paper we mainly focus on the second one. Indeed, the variability in the concern specification depends on the expressiveness of the meta-model dedicated to concern modeling. Consequently, a reasonable solution to integrate variability in the concern model can be inspired by product line research and more precisely by [14].

To introduce variability in the weaving process, the composition meta-model of our AOM approach has been extended. These extensions concern the adaptations primitives and the pointcut specification. They are composed of a set of entities specifying optional parts, alternatives, dependencies and mutual exclusion constraints. These extensions allow the user to design a family of aspects at the design level that can be derived to be applied in a particular context.

One of the main benefits of building a composition protocol is the capability to control and guide the software architect when he designs new applications. The variability introduction does not affect the guidance and the control when reusing a derivable concern. On the contrary, the choices induced by the addition of variability are also controlled and guided thanks to the expressiveness of the composition protocol.

In the SmartAdapter platform, we plan to improve the target definition. In the future release, this target will be described with a template model in which it will be possible to add constraints. These features will allow the designer to describe precisely the different integration contexts. Besides, at present time we have defined our extensions only for a meta-model dedicated to the composition of both programs and models based on the SmartAdapter approach. We plan to generalize the approach to various AOM approaches. Finally, AOM approaches can be used to manage variability in software product line. Our work can be merged to these approaches to show why variability is also needed in the aspects in order to use an AO approach to build software product line.
